The genesis of East Elba iron ore deposits and their interrelation with Messinian tectonics

Dissertation zur Erlangung des Doktorgrades der Naturwissenschaften

an der Geowissenschaftlichen Fakultät der Eberhard-Karls-Universität Tübingen

Vorgelegt von Ines Dünkel aus Villingen-Schwenningen

 $\boldsymbol{2002}$

Acknowledgements

I would like to thank my supervisors Prof. Dr. Wolfgang Frisch and Dr. Joachim Kuhlemann for their continuous support, their engagement, for the helpful discussions and the examination of this work.

I very much approved the good collaboration and interchange with Dr. Volker Lüders (Geoforschungsinstitut Potsdam) and Prof. Dr. Torsten Vennemann (Institut de Minéralogie et Géochimie, Univérsité de Lausanne), Dr. Marco Benvenuti (Dipartimento di Scienze della Terra Firenze) and Dr. Vincenzo Pascucci (Dipartimento di Scienze della Terra Siena) during the implementation and evaluation of this study. For analyzing and commenting on the respective chapter of fluid inclusions, thanks to Dr. Volker Lüders (Geoforschungsinstitut Potsdam).

My special thanks are directed to to all the people, who have kindly supported me during my interdisziplinary work. In this context I am thankful to Prof. Dr. Gregor Markl, Dr. Udo Neumann und Michael Marks for their time and efforts.

I owe a lot to my colleagues and would like to thank the complete Ak-Frisch group for the agreeable atmosphere. I also appreciate very much Dr. Balázs Székely's computer knowledge and reading of my work.

Furthermore I would like to thank all the helpful people in the laboratories. Without their help I would not have been able to finish this work as fast as I did.

Thanks to the mining company "Società delle miniere della comune di Rio Marina" and especially to Sig. Cillerai for the cooperativeness and the indispensable work permit. Without their encouragement, no study of the Elbanean deposit would have been available.

Financial support for this work was provided by the Deutsche Forschungsgemeinschaft, Project No. Ku 1298/1-2.

Finally I thank my parents and my grandmother for their long-lasting assistence and Uwe for all the discussions, advices and ideas to support me, for his perfect system administration and for the endless encouragement he offered me.

Summary

The iron ore deposits of eastern Elba were formed contemporaneously with late Miocene (Messinian) shallow granitoid emplacement, intruding into a series of previously regionally metamorphosed gneisses, marbles and marble-bearing schists. Due to metasomatic and hydrothermal processes extensive deposits of Ca-Fe-skarns and Fe-ores emerged. The primary preconcentration of iron is synsedimentary (late Paleozoic-Triassic). The N-S trending belt of iron ore deposits in east Elba, mainly containing hematite, magnetite and pyrite, show a S-N temperature zoning.

The Miocene pyrometasomatic to hydrothermal mineralization, associated with skarn formation, precipitated at temperatures which did not exceed 600°C. As a consequence of the associated increase in rock permeabilities, intense metasomatic-hydrothermal activities along the transport channels caused a remobilization of the iron-bearing surrounding rocks and a redeposition in skarns and iron ore deposits.

Analyses of the observed mineral parageneses show that metasomatism continuously took place under gradually decreasing temperatures, low O₂ fugacity and Fe-saturated, hydrothermal solutions. Fluid inclusion studies prove that the metasomatic fluids were high saline brines with dominantly magmatic origin, northward mixed with marine-evaporitic water. The δ^{34} S values are typical for a magmatic source and high fluid:rock ratios. Also the oxygen isotope ratios of quartz, magnetite and andradite indicate high fluid:rock ratios. Apparently a saline solution percolated in convection cells preferrably along cracks and fractures in the permeable solid rock system, transporting heat from the plutonic body.

Quantitative comparison of the mass exchanges between the granodiorite pluton and the surrounding rocks confirm, that the metasomatic system was an open system, with metal-sources outside the pluton. The metal content is primary of sedimentary origin, remobilized from the Verrucano formation and redeposited preferably along main N-S-striking faults, crosscutting eastern Elba.

The mineralization and skarnization of Ginevro and Sassi Neri as well as of Capo Calamita, Terra Nera, Rio Marina and Rio Albano took place after the gravitational gliding of Flyschnappes from the Monte Capanne pluton. The chemical composition of iron oxides and silicates, the high fluid:water ratio, the fluid composition and the isotopic signatures support a one-phase formation model for all localities and all occurring mineral generations.

Two types of iron ore deposits can be distinguished: The deposits of Ginevro and Sassi Neri are skarnified and mineralized in an autochthonous position, underlain by the shallow Porto Azzurro pluton (south-east of Elba). The second type of iron ore formation, containing the allochthonous deposits of Capo Calamita, Terra Nera, Rio Marina and Rio Albano, were probably mineralized and skarnified at the eastern flank of or east of the Monte Capanne pluton (West Elba).

Zusammenfassung

Die Genese ostelbanischer Eisenerzlagerstätten steht in engem Zusammenhang mit Miozäner Extensionstektonik und der daraus resultierenden Platznahme granitischer Plutone in eine Serie schwach regionalmetamorpher Gneise, Marmore und Schiefer. Die mesozoischen Gesteine Ostelbas beherbergen sechs ehemals bedeutende, entlang NS-verlaufender Störungszonen auftretende Eisenerzlagerstätten. Die pyrometasomatisch-hydrothermalen Vererzungen sind teilweise mit Skarnen vergesellschaftet und zeigen einen N-S gerichteten Temperaturtrend in Abhängigkeit ihrer Distanz zum Pluton.

Es lassen sich verschiedene Typen und Generationen von Eisenoxiden und Eisensulfiden unterscheiden, die eine einphasige Abkühlung bei schwankenden und insgesamt niederen O₂-Fugazitäten aufgrund hydrothermaler Zirkulation großer eisenreicher Fluidmengen belegen. Für alle Lagerstätten konnte eine magmatische Schwefelquelle bewiesen werden, welche nach Norden mit zunehmender Distanz zum Pluton zunehmenden Einfluss sedimentären Schwefels zeigt. Untersuchungen der Fluid Einschlüsse zeigen hohe Salzgehalte eines magmatisch dominierten Fluids. Laserablation an kogenetischer Mineralpaaren bestätigen ein hohes Fluid:Gesteins Verhältnis, so dass von einem Fluid dominierten Konvektionssystem in Abhängigkeit von Permeabilität und Tektonik des durchströmten Gesteins ausgegangen wird.

Aufgrund der tektonischen Situation und der vorherrschenden Paragenesen können zwei Typen von Eisenerzlagerstätten unterschieden werden. Die Lagerstätten von Ginevro und Sassi Neri bildeten sich autochthon über dem südöstlich Elbas gelegenen Porto Azzurro Pluton, während die allochthonen Lagerstätten von Capo Calamita, Terra Nera, Rio Marina und Rio Albano bis 5.5 km entlang der Zuccale Detachment Fault nach Osten transportiert wurden. Die allochthonen Lagerstätten vererzten und verskarnten östlich des Monte Capanne Plutons (West Elba), nach dem Abgleiten der Flysch-Decken nach Osten.

Die ähnliche Elementverteilung der Eisenoxide und Eisensulfide in allen Lagerstätten beweist große Fluidmengen mit geringen Schwankungen, der Chemismus der Fluid Einschlüsse und die Isotopenfraktionierung bestätigen eine einphasige Genese eines magmatisch dominierten Fluids für alle Lagerstätten.

Die primären Eisenerzanreicherungen wurden aus den Triassischen Sedimenten des Verrucano remobilisiert und vorzugsweise entlang der für Ostelba charakteristischen N-S streichenden Störungssystemen sekundär ausgefällt.

List of Figures

1.1	Geological map of Elba after BARBERI et al. (1967) showing the tectonic com- plexes and the 6 main iron ore deposits. The Monte Capanne pluton dominates the western part of the island.	2
1.2	Geological map showing the tectonic complexes of eastern Elba defined by TREVISAN (1950), major tectonic structures and the iron ore deposits. The dashed line outlines the supposed position of the Porto Azzurro pluton (BAR-BERI et al., 1967; DESCHAMPS et al., 1983b).	3
1.3	Pluton emplacement and tectonic evolution of Elba island (Miocene - recent) with subvolcanic granitoides and "gravitational" transport (from W towards E) of flysch nappes, afterNOHLEN (1998). The Complexes I - V after TREVISAN (1950) are described in the text.	5
1.4	Stratigraphic positions and country rocks of iron ore deposits. Comp.: Tectonic complexes defined by TREVISAN (1950), see also Fig. 1.2. Complex II and III are separated by a serpentinite-bearing overthrust zone. Prior to in-sequence thrusting and extension, the Tuscan units (Comp. I - III), were located W of unit I (Fig. 1.3). ZDF: Zuccale Detachment Fault.	6
2.1	Schematic geological overview of the different lithologies of the Calamita penin- sula with major tectonic structures. There are hints that the Calamita Schists can be subdivided internal into two tectono-stratigraphic units: Into the muscovit biotite schists from the eastern part of the Calamita peninsula and into an undifferentiated basis, after DADEDE et al. (1967)	e-
2.2	Mineral assemblages and sequences versus time of Elba iron ore deposits from the north (a, Rio Albano) to the south.	10
2.3	Multiply zoned magnetite (mag I) from the Ginevro deposit. Dark zones and cores are preferably replaced along cracks by younger, iron-rich amphibole (amph) of pargasitic composition (back-scattered electron image).	13
2.4	Subtly zoned magnetite (mag I) beside a tremolite (with distinct cleavage) vein	10
2.5	From the Ginevro deposit (long side 550 μ m)	13
2.6	Zoned magnetite margins (mag II) overgrowing older and altered mushketovite (mag I). Capo Calamita deposit (back-scattered electron image)	16
	(10

2.7	Mushketovite (mag I) including relict pyrite (py I), overgrown by younger magnetite II, Capo Calamita deposit (long side 550 μ m, oil immersion)	17
2.8	Skarn body of the Capo Calamita deposit (Punta della Calamita), with mainly banded ferro-actinolite and black ilvaite.	17
2.9	Magnetite (mag II), partly oriented hematized to hem II, with chalcopyrite (cpy) and pyrrhotite (pyrr), from the Capo Calamita deposit (long side 550 μ m, oil immersion)	17
2.10	Early formed cassiterite in magnetite I, locally with maghemite (magh) in veins. The magnetite is overgrown by hematite margin (partly martite) and lamellar minerals of specularite (spec), Terra Nera deposit (long side 550 μ m, oil immersion).	18
2.11	Zoned and partly maghemized (magh) magnetite of the oldest generation (mag I) is surrounded by younger magnetite (mag II), which is replaced by recrystallized hematite (hem II), Terra Nera deposit (long side 550 μ m, oil immersion).	18
2.12	Oriented hematitization (martite) of grey-purple magnetite (mag II) locally with bluish maghemite, besides lamellar specularite (spec), Terra Nera deposit (long side 550 μ m, oil immersion).	19
2.13	Remnant magnetite core in clearly zoned hematite II from the Terra Nera deposit (long side 550 μ m, oil immersion).	19
3.1	Classification of mica of the country rock. a) Muscovite from the Calamita Schists (C 385), surrounding Ginevro, Sassi Neri and Capo Calamita. b) Biotite from the Verrucano formation near the Rio Marina deposit (V 11)	25
3.2	Classification of primary feldspar of the Calamita Schists (C 385) and of late adularia in joints of the Calamita Schists (LP 1) and the Rio Marina (V 2, V 11) deposit.	26
3.3	Pyroxene classification from the Ginevro deposit showing a) salitic cores and rims of ferrosalitic composition (G 282, $n = 34$). b) Note the small element changes in the optically zoned pyroxene (G 282b) of the same ferrosalitic composition like the rims in G 282a.	27
3.4	Classification of pyroxene: a) Salite from the country rock (Calamita Schists) surrounding the southern deposits (Ginevro, Sassi Neri and Capo Calamita) and b) Ferrosalite from the Capo Calamita deposit. Note that no zoned minerals were found within the deposit (as in Fig. 3.3).	28
3.5	Zoned Ca-amphiboles with pargasite cores as well as rims and veins of tremolitic composition from the Ginevro deposit; classification after LEAKE et al. (1997).	30
3.6	Amphibole from the Ginevro deposit besides cataclastic garnet crystals. Note the small pargasitic remnants (dark coloured) surrounded by amphibole of tremolitic composition (light), and chlorite (chl) as product of alteration (back- scattered electron image).	31
3.7	Zoned amphibole in veins from the Ginevro deposit. Note the core of pargasitic composition with its distinct cleavage (situated in the center), surrounded by a small, lighter tremolitic rim with imperfect cleavage (transmitted light, G 127).	31

3.8	Relation between composition and paragenesis of calcium amphiboles after HALLIMOND (1943) Grev: limestone as parent rock. The paragasite (NaCaa	
	$(Mg, Fe^{2+})_4Al_3Si_6O_{22}(OH)_2)$ and tremolite composition $(Ca_2(Mg, Fe^{2+})_5Si_8O_{22})$	
	$(OH)_2$) indicates limestones as parent rocks for Ginevro and Sassi Neri. Filled	
	triangle: pargasite cores, open triangle: tremolite rims from the Ginevro and	
0.0	the Sassi Neri deposit.	32
3.9	Zoned Ca-amphiboles from the Sassi Neri deposit with pargasite cores and rims of tremolitic composition: classification after LEAKE et al. (1997)	32
3.10	Replacement of pyroxene, preferrably along cracks in garnet, to uralite of acti-	-
	nolitic composition from the Capo Calamita deposit (back-scattered electron	0.0
9 1 1	Image, C 303).	33
5.11	ot al. (1007) The entirely observed mineral zenation (serve and rim) lies	
	below the detection limit or is not based on element constion	24
2 1 9	Ca amphibales of tramplitic composition from the deposit II Porticciale, south	94
0.12	of the Bio Marina denosit: classification after LEAKE et al. (1007)	35
3 13	Needles of tremolite (amph) with pyrrhotite (pyrr) and calcite (cc) in the inter-	00
0.10	stices from the Il Porticciolo skarn. The pyrrhotite shows brittle deformation	
	(reflected and transmitted light)	35
3.14	Classification of garnet after RICKWOOD (1968), samples from the Ginevro	00
	deposit. The grossular shows an average of XCa about 0.73 and XFe about	
	0.23, and no variation in composition.	37
3.15	Unzoned cataclastic and radiie of rock-forming dimension with calcite and mag-	
	netite in the interstices, Capo Calamita deposit (back scattered electron image).	38
3.16	Classification after RICKWOOD (1968) of unzoned garnet from the Capo Calamita	
	deposit. The and radite shows an average of XCa about 0.97 and XFe under 0.03.	38
3.17	Classification after RICKWOOD (1968) of multiply zoned garnet from the Capo	
	variance in XFe up to 0.05	30
3 18	Hypidiomorphic multiply zoned andradite from the Capo Calamita denosit	59
0.10	which is partly replaced by ferro-actinolite besides small magnetite crystals	
	(back scattered electron image)	39
3.19	Needles of mushketovite surrounded by subtly zoned younger magnetite from	00
0.10	the Capo Calamita deposit (back scattered electron image). The element vari-	
	ations of the marked profile line is presented in Fig. 3.20	46
3.20	Element variations of mushketovite from the Capo Calamita deposit (mag I,	
	core; step-width: 4μ m; Ca 12b). For the position of the profile line see Fig.	
	3.19. There is only little enrichment of Si and Al in pure magnetite. The other	
	elements are below the detection limit	48
3.21	Euhedral magnetite crystals are included in multiply zoned and radite or en-	
	riched in the foliation of the skarnified host rock, Capo Calamita deposit (back	
	scattered electron image)	48
3.22	Zoned magnetite margins (mag II) from the Capo Calamita deposit. Dark	
	zones are enriched in Si, Al, Mg and Ca (compared with light zones); back	
	scattered electron image.	50
3.23	Element distribution of the Capo Calamita iron oxides in their mineral forming	. .
	sequence versus the element content (mean values)	50

3.24	Oxide concentration of the Terra Nera iron oxides in their mineral forming sequence. The high value of SiO_2 of the magnetite I cores (mean 2.0 wt%) are listed in Table 3.9.	52
3.25	Hematite pseudomorph with relict magnetite besides lamellar specularite from the Terra Nera deposit (ES 42, long side 550 μ m).	52
3.26	Partly ductile deformed as well as broken lamellar specularite between magnetite crystals from the Terra Nera deposit (long side 1100 μ m).	52
3.27	Remnants of magnetite in hematite besides lamellar specularite from the Rio Marina deposit (V 14, back scattered electron image).	53
3.28	Magnetite replaced by multiply zoned hematite from the Rio Albano deposit (back scattered electron image)	54
4.1	Zonation of classic skarns depending on geometry of the pluton and the fluid flow. The proximal exoskarn is dominated by garnet and the distal skarn con- tains more pyroxene. The complete legend is listed in Fig. 4.2 (after MEINERT, 1992)	58
4.2	Evolutionary stages of pluton-associated skarn deposits: a) Initial intrusion causes metamorphism of sedimentary rocks. b) Metamorphic recrystallization and phase changes reflect protolith composition. Diverse calc-silicate minerals were formed by fluid circulation in impure lithologies and along fluid boundaries. c) Crystallization and dissolution of an aqueous phase result in fluid-controlled metasomatic skarn. d) Cooling of the pluton and the circulation of meteoric water causes (mainly in shallow zones) retrograde alteration of metamorphic and metasomatic minerals (after MEINERT, 1992).	59
4.3	Ductily deformed Calamita Schists surrounding the Ginevro iron ore deposit, 30 m NN, W flank of the mining area	61
4.4	The Capo Calamita deposit: (1) Civetta, (2) Albaroccia, (3) Nuova zona, (4) Macei Alto, (5) Polveraio, (6) Coti Nere, (7) Le Piane, (8) Punta Rossa, (9) Macei Basso, (10) Vallone Alto, (11) Vallone Basso (after CALANCHI et al., 1976).	63
4.5	Geological map with major faults and skarn deposits of the Capo Calamita deposit (after DÜNKEL, 2001). Three skarn bodies can be distinguished: Punta della Calamita, Vallone Alto (south of Palazzo) and Nuova Zona. In Vallone Basso an epidote skarn is observed, followed by a garnet-pyroxene-skarn with magnetite towards the north. In the Nuova Zona an almost monomineralic garnet skarn is exposed.	64
4.6	Ilvaite crystals from the Capo Calamita deposit, showing a distinct pleochroism from reddish-brown to yellowish-brown in reflected light. White: Magnetite replacing ilvaite. (Width = $550 \ \mu m$, oil immersion).	65
4.7	Projections of log f_{O_2} - temp stability range of pure andradite and pure heden- bergite at 2 kbars fluid pressure. The region between the two univariant curves indicates the f_{O_2} - temp range where both phases can coexist (after GUSTAFSON, 1974). Note the maximum range of estimated values of f_{O_2} be- tween 10 ⁻¹⁸ bar (hedenbergite in) and 10 ⁻³³ bar (andradite out) relevant for the reaction andradite-hedenbergite in Elbanean skarns	70

- 4.8 Temperature versus log f_{O_2} stability diagram for a hedenbergitic composition, comparable to the Elbanean conditions, at 4 kbar. The solid line corresponds to the stability boundary (after REDHAMMER et al. (2000)). Note that the temperatures of the Elbanean deposits did not exceed 600 °C (Chapter 5); HM: Hematite-magnetite buffer; QMF: Quartz-magnetite-fayalite buffer. . . .
- 4.10 Stable isobaric invariant points involving the phases andradite (Ad), hedenbergite (Hd), quartz (Qt), magnetite (Mt), wollastonite (Wo), xonotlite (Xo; Ca₆(Si₆O₁₇)(OH)₂), kirschsteinite (Kr; CaFeSiO₄), ilvaite (Iv) and vapor (fluid; V). The grey dot locates the isobaric invariant point of the relevant coexisting phases Ad + Hd + Qt + Mt + Iv + V for Elbanean skarns (from GUSTAFSON (1974)).
 73
- 4.12 Sulfur activity of different iron oxides versus temperature. The fugacity corresponds to the activity, describing the effective sulfur concentration under nonideal conditions (BARNES, 1979). For example at temperatures below 500°C: formation of pyrite at relatively high a_{S_2} . Hematite occurs at decreasing a_{S_2} , while magnetite precipitates at lower a_{S_2} , increasing f_{O_2} or at higher temperature.
- 4.13 log f_i temperature pressure relations of the hematite-magnetite-pyrite-H₂O buffering assemblages at 1, 5 and 10 kbar. H₂S is the dominant S-bearing species in the fluid phase at low temperatures and SO₂ is the most abundant S-bearing species at high temperatures; $f_i = f_{SO_2}$ or f_{H_2} or f_{H_2S} or f_{H_2O} (from SHI, 1992).

71

75

75

4.16	The $f_{O_2} - a_{CO_2}$ diagram (Fig. 4.17) showing the involved reactions (Table 4.1) in order to clarify the various Ca-bearing skarn assemblages ranging between (a) 600°C, (b) 500°C, (c) 400°C and (d) 300°C. The diagram is based on a pressure of 1 kbar and calculated activities of $a_{and} = 0.8$, $a_{hed} = 0.8$, $a_{cc} = 0.9$ and $a_{Fe-act} = 0.06$. The position of invariant points shift with decreasing tem- perature towards lower f_{O_2} and lower a_{CO_2} values. Grey dots: Invariant points of hedenbergite (hed), ferro-actinolite (Fe-act), magnetite (mag), quartz (qtz). Note the increasing stability field in-between the invariant points during cooling of the system.	79
4.17	The zoomed $f_{O_2} - a_{CO_2}$ diagram (out of Fig. 4.16) shows the reactions (1)-(5), Table 4.1 together with the synthetic fayalite-magnetite-quartz (FMQ) buffer curve in order to clarify the various Ca-bearing skarn assemblages. In the range of 300-600°C the position of the invariant point (ferro-actinolite) shifts with decreasing temperature towards lower f_{O_2} and a_{CO_2} values (grey dots) from log $f_{O_2} = -22.4$ bar at 600°C to -38.2 bar at 300°C, while log a_{CO_2} changes from -0.1 at 600°C to -2.2 at 300°C. Dotted lines: Exemplarily shown reaction lines for 400°C and $a_{hed} = 0.05$.	80
5.1	Variation of sulfur isotopic composition (δ^{34} S values in $\%_0$) in rocks, waters and volcanic gases from HOEFS (1997), compared to those of Elbanean pyrites, pyrrhotites and chalcopyrites made by Erz (2000) and in this study	86
5.2	Sulfur isotopic composition of pyrite and pyrrhotite (Il Porticciolo) from different deposits from N to S; number of measurements = 123 , after Erz (2000).	88
5.3	Calculated temperatures of δ^{18} O (in $\%$) of coexisting quartz-magnetite (qz- mag) and magnetite-andradite (and-mag) mineral pairs for several east Elba iron ore deposits, depending on oxygen isotope fractionation. Fractionation factors after ZHENG & SIMON (1991); ZHENG (1991, 1993). Black: Major tectonic lines	94
5.4	Isotopic composition of carbon (δ^{13} C) versus oxygen (δ^{18} O) in ‰ for Elbanean marbles depending on their distance to to the skarnified or mineralized contact. The 25 plotted δ^{18} O and δ^{13} C values from the Capo Calamita deposit (Vallone Basso, Vallone Alto, Laveria) and the Rio Marina skarn are listed in Table 5.5. Encircled: Main distribution of less altered Elbanean marbles.	97
5.5	Isotopic composition of carbon (δ^{13} C) versus oxygen (δ^{18} O) in ‰ for Elbanean marbles, limestones, calcite veins, breccias and interstices from Capo Calamita and Rio Marina (Table 5.6 and Table 5.5). Grey: Main distribution of calcite veins, breccias and interstices	98
6.1	Fourier transmission infrared (FTIR) spectra showing differences in infrared transmittance versus wavelengths of hematite and magnetite from different locations (after LÜDERS, unpubl. data).	105
6.2	Fourier transmission infrared (FTIR) spectra showing the differences in the infrared transmittance versus wavelengths of hematites from the Terra Nera (ES 37) and the Rio Marina deposit (M 233).	106

6.3	Sequence of transmitted IR light microphotographs of hematites from Elba Is- land. Rio Marina deposit: a) growth zones in hematite (hub); b) characteristic two-phase fluid inclusion with irregular shapes and high relief (hub 2); c) rare primary two-phase fluid inclusion (M 233). Terra Nera deposit: d) character- istic "necking down" of two-phase fluid inclusions (ES 36); e) zoned hematite with patchy IR transparency. The zonation is roughly oriented perpendicular to the lamination (ES 45). Rio Albano deposit: f) secondary FIs oriented along a trail in lamellar hematite (R 208).	108
6.4	Cation compositions of fluid inclusions in hematite, specularite and magnetite from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano plotted in terms of major cation relations. The numbers refer to AAS-measurements listed Table 6.2.	111
7.1	The island of Elba with emplacement of the Monte Capanne granodiorite into a series of previously regionally metamorphosed gneisses, in marbles and marble- bearing schists. The tectonic Complexes I - V are classified after TREVISAN (1950). The dashed line outlines the supposed position of the Porto Azzurro pluton	116
7.2	a) Model of late Miocene shallow magmatic-hydrothermal ore formation with schematic precipitation and presumed surface. Arrows indicate the thermal convection, representing the fluid transport. b) Simplified profile of the expected environment of the Capo Calamita deposit fractures, older N-S striking faults in the Calamita Schists, and the parauthochtonously overlying slices of mainly mineralized Upper Triassic " <i>calcare cavernoso</i> " (Chapter 1, Fig. 1.4). Scale: Horizontal distance ca. 2 km, vertical distance ca. 1 km (?)	116
8.1 8.2	Schematic profile of south eastern Elba with the deposits of Ginevro and Sassi Neri with the Porto Azzurro Pluton of quartzmonzonitic composition. The de- posits are located in the cristalline basement of the Calamita Schists (Complex I). Scale: Horizontal distance ca. 10 km, vertical distance ca. 1 km Genetic model for the iron ore formation of Ginevro and Sassi Neri. The late Miocene shallow magmatic-hydrothermal iron remobilization and redeposition	122
8.3	preferrably along the east Elbanean N-S-striking fault system is caused by the Porto Azzurro Pluton. The deposits are located in the cristalline basement of the Calamita Schists (Complex I), with carbonate-bearing tectonic wedges of Complex II. Scale: Horizontal distance ca. 5 km, vertical distance ca. 1 km Geological map of Elba after BARBERI et al. (1967) showing the tectonic com- plexes, the 6 main iron ore deposits as well as minor skarnified and mineralized localities (black dots), which appear exclusively east of the Monte Capanne pluton. The dashed line outlines the supposed position of the Porto Azzurro	122
	pluton (BARBERI et al., 1967; DESCHAMPS et al., 1983b).	123

List of Tables

2.1	Microprobe analyses (in wt%), of magnetite (mag) generations from the Capo Calamita and the Terra Nera deposit. Note the remarkable enrichment in silicon; $n =$ number of measurements.	15
3.1	Detected elements, measured by electron microprobe analyzer (Jeol JXA 8900) with common (ASTIMEX) standards.	24
3.2	Summary of pyrometasomatic to hydrothermal minerals, their replacements and alteration products	24
3.3	Mean and maximum values in wt% of garnet from the Capo Calamita and the Ginevro deposit. The multiple zonation (Capo Calamita: C 373, n = 32 and C 303, n = 113) is based on variable oxidation level of Fe ²⁺ and the substitution of Fe ²⁺ by Al ³⁺ . The Fe ³⁺ content is calculated after RYBURN et al. (1976). Alm: almandine, and: andradite, gros: grossulare, pyp: pyrope, sps: spressartine.	37
3.4	Chemical composition of ilvaite from Rio Marina (R. M.) and the Capo Calamita (C. C.) deposit, as well as measurements from Beran (1980) and Carrozini (1994) from the Rio Marina skarn (R. M. skarn), n.d. = no data. The proportion of Fe^{2+} to Fe^{3+} is stoichiometrically calculated after DROOP (1987) and STRUNZ (1966)	40
3.5	Mean values of epidote from the Capo Calamita (C 103, $n = 8$) and the Ginevro deposit (G 282; $n = 2$). Note the small chemical differences between the deposits.	42
3.6	Results from the chemical composition of allanite in wt% from the Ginevro deposit (G 282, $n = 5$)	43
3.7	Mean element oxide concentrations of Elbanean iron oxides from the oldest (I) to the youngest (III) generation, in wt%	47
3.8	Oxide concentration of magnetite subgenerations from the Capo Calamita deposit. Presented are mean and maximum values in wt $\%$, n.d. = no data	49
3.9	Oxide concentration of magnetite subgenerations from the Terra Nera deposit. Presented are mean and maximum values in wt%.	51
3.10	Oxide concentration of the Rio Marina iron ore generations. Presented are mean and maximum values in wt%.	54
3.11	Oxide composition of the Rio Albano deposit. Presented are the mean and maximum values in wt%. Note that only specularite shows little enrichment in Al_2O_3 .	55

LIST OF TABLES

4.1	Mineral reactions involving magnetite (mag), hedenbergite (hed), and radite (and), ferro-actinolite (Fe-act), calcite (cc) and quartz (qtz). The diagram is based on a pressure of 1 kbar, calculated activities of $a_{and} = 0.8$, $a_{cc} = 0.9$, $a_{Fe-act} = 0.06$ and the max. value of $a_{hed} = 0.8$.	78
4.2	Mineral reactions involving magnetite (mag), hedenbergite (hed), and radite (and), ferro-actinolite (Fe-act), calcite (cc) and quartz (qtz). The diagram is based on a pressure of 1 kbar, calculated activities of $a_{and} = 0.8$, $a_{cc} = 0.9$, $a_{Fe-act} = 0.06$ and the min. value of $a_{hed} = 0.05$, representative for the east flank of the Capo Calamita deposit.	80
5.1	Sulfur isotopic composition (δ^{34} S, relative to Cañon Diablo Troilite (CDT), ± 0.3 error) of pyrite, pyrrhotite and chalcopyrite from different Elbanean de- posits; number of measurements = 10. Note the decrease in δ^{34} S values from N (Rio Marina) to S (Capo Calamita) and the low values of the earlier ("older", see Chaper 2) species of chalcopyrite	87
5.2	δ^{18} O analyses (in ‰) of coexisting quartz, and radite and magnetite from the east Elba iron ore deposits from south (Ginevro) to north (Rio Albano), measured by laser ablation; in brackets: uncertain values of poor balance, less material or - applying for quartz-magnetite in Ginevro: isotope ratios which exclude cogenetic formation; $n.d =$ not detected	92
5.3	Mean values of δ^{18} O analyses (in $\%_0$) of coexisting quartz and magnetite from south (Capo Calamita) to north (Rio Albano) deposits, combined with calculated temperatures for each mineral pair.	92
5.4	Mean values of δ^{18} O analyses (in $\%_0$) of coexisting and radite and magnetite from south (Ginevro and Capo Calamita), combined with calculated temperatures for each mineral pair.	93
5.5	δ^{18} O and δ^{13} C analyses (in ‰) of unskarnified marbles and limestone profiles depending on the distance to the intrusive contact from the Capo Calamita deposit and the Torre di Rio Marina skarn.	98
5.6	δ^{18} O and δ^{13} C analyses (in ‰) of calcite veins, breccias and interstices from east Elba iron ore deposits and skarns, documented from north (Rio Albano) to south (Ginevro).	99
5.7	δ^{18} O and δ^{13} C analyses (in ‰) of unaltered Messinian marine and lacustrine limestones from Rosignano, Tuscany.	99
6.1	Summary of mean microthermometric data (in °C) of primary fluid inclusions in hematites from the Terra Nera (ES) and the Rio Marina (Hub, M) deposit. Abbreviations: T_e : first ice melting temperature, $T_{m,ice}$: final ice melting temperature, T_h : homogenization temperature, n.d.: no data	109
6.2	Element content (in ppm) of calcium (Ca), magnesium (Mg), potassium (K) and sodium (Na) of fluid inclusions in hematite (hem), specularite (spec) and magnetite (mag) from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano made by atom-absorption-spectrometry. Bold: Major iron ore generation (see Chapter 2). Beforence applying of symplectical quarta grains	
	generation (see Chapter 2). Reference analyses of synthetical quartz grains and H_2O_{bidest} are also listed.	110

XIV

LIST OF TABLES

6.3	The NaCl : KCl : CaCl ₂ ratios of fluid inclusions in hematite, specularite and magnetite from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano, based on Table 6.2.	111
A1	Microprobe analyses of zoned magnetite I (core, $n = 55$) from the Ginevro deposit (G 128)	A1
A2	Microprobe analyses of magnetite II from the Ginevro deposit (G 399, G 399a,	
A3	n = 79)	A10
-	399a, n=79)	A15
A4	Microprobe analyses of magnetite I from the Capo Calamita deposit (n=81) .	A19
A5	Microprobe analyses of magnetite II from the Capo Calamita deposit $(n=179)$	A24
A6	Microprobe analyses of magnetite III from the Capo Calamita deposit $(n=39)$	A34
A7	Microprobe analyses of magnetite I from the Terra Nera deposit (ES 61, ES57)	A37
A8	Microprobe analyses of magnetite from the Rio Marina deposit $(n=61)$	A39
A9	Microprobe analyses of magnetite from the Rio Albano deposit (R 208, n=90)	A43

Chapter 1 Introduction

1.1 Overview

Numerous genetic models of ore formation on Elba as the westernmost part of the Tuscan magmatic province have been proposed since the first presentations of LOTTI (1884, 1886). The metallogenesis of the Elba mining district is still under discussion (DESCHAMPS et al., 1983b; ZUFFARDI, 1990, 1994; DURANTI et al., 1992; PERTUSATI et al., 1993). WIJKERSLOOTH (1934) proposed a general model in which the ore deposits of Tuscany are related to the "overthrusting" plates during Miocene- Pliocene tectonic activity. The variety of complex mineralization histories led to a controversy about the origin and evolutionary paths of ore mineral assemblages (DIMANCHE & RUIZ, 1969; DIMANCHE, 1970). The variety of arguments is mainly based on the unknown sources of iron and sulfur, which are assumed to be either of sedimentary (LOTTI, 1886; STELLA, 1933; DIMANCHE, 1970; ZUFFARDI, 1990; DIMANCHE & BARTHOLOMÉ, 1969) or magmatic origin (BODECHTEL, 1965; ARNOLD, 1976; BODECHTEL & KLEMM, 1965; BENVENUTI et al., 1986, 1994; ERZ, 2000). A number of arguments for this dispute derived from research on the island of Elba, hosting about six formerly economic iron ore deposits (Fig. 1.1, 1.2), which were exploited for more than 2000 years.

• The mineralizations are, like the Tuscan deposits Bocchegiano, Niccioleta, Gavorrano (DALLENGNO et al., 1979; PUXEDDU et al., 1984; BENVENUTI et al., 1992) interpreted as a result of contact metamorphism, combined with mobilization of hematite and pyrite from Permo-Triassic rocks bearing carbonate lenses (DIMANCHE, 1971; DIMANCHE & BARTHOLOMÉ, 1969; DIMANCHE, 1974b). The Elba deposits are generated by hydrothermal activity related to the Messinian granodioritic intrusion. In this case, the granodioritic intrusion is not the source of the ore because the granodiorite is unlikely to contain such volumes of iron.

The skarn-type deposits (Capo Calamita, Ginevro, Sassi Neri) are replacements in different calcite-rich levels, whereas the northern deposits (Terra Nera, Rio Marina, Rio Albano) show hydrothermal impregnations of quartzitic country rocks (BENEO, 1952; DEBENEDETTI, 1953).

• A second theory is based on pre-existing (relative to the Messinian intrusion) isolated iron ore concentrations for the southern deposits (Ginevro and Sassi Neri). The authors propose primary ore enrichment as a product of former magmatic differentiation (for

Figure 1.1: Geological map of Elba after BARBERI et al. (1967) showing the tectonic complexes and the 6 main iron ore deposits. The Monte Capanne pluton dominates the western part of the island.

example lamprophyres in Ginevro; DIMANCHE & RUIZ (1969); DIMANCHE (1971)).

- BODECHTEL (1965) proposed magmatic segregation considering a volcano-sedimentary origin similar to the Triassic rift volcanism in northern Tuscany (SERRI et al., 1991; RICCI & SERRI, 1975). The iron ores bound to different Carboniferous-Triassic series might have formed epigenetically in latest Triassic time (Rhetian) according to BODECHTEL (1965); BODECHTEL & KLEMM (1965), and pre-intrusive relative to the Messinian Porto Azzurro pluton, with subsequent contact metamorphic overprint.
- According to ZUFFARDI (1990, 1994), the primary iron ore enrichments are of sedimentary origin, related to the stratiform occurrence of the ore bodies in Ginevro, Sassi Neri and Terra Nera. Subsequent tectonic activity and a metamorphic overprint resulted in intense deformation of ore bodies and new mineral associations. For this reason PERRIN (1975) misinterpreted the deformed Ginevro deposit as vein-type mineralization.

In southern Tuscany, a comparable genetic environment of ore formation (T = 450 °C, pressure of a few hundred bars, presence of fracturing) with sulfide and oxide mineralizations has been observed (TANELLI, 1983; BENVENUTI et al., 1990; TANELLI et al., 1991; LATTANZI et al., 1994), related to Miocene shallow intrusions. The pyrometasomatic activity in Elba resulted in exoskarn formation prior to ore mineralization. The skarns are classified by EINAUDI et al. (1981); EINAUDI & BURT (1982) as igneous metasomatic skarn in continental orogenic belts, linked to subduction related I-type magmas BOUILLIN et al. (1993). According to EINAUDI et al. (1981); EINAUDI & BURT (1982), the size of these massive exoskarn bodies and their sharp contacts to the country rocks without a skarn can not be explained by autometasomatic genesis. Depending on porosity and permeability of the fluid saturated host rock, reaction fringes emerge, which obstruct the dispersion of the fluid reaction front, focusing the fluid flow path in the direction of maximum permeability (DIPPLE & GERDES, 1998). LOPEZ-RUIZ et al. (1969) and DIMANCHE (1969, 1971) found that the ore bodies of Ginevro and Sassi Neri represent the product of replacement of calcareous lenses within the Paleozoic basement

Figure 1.2: Geological map showing the tectonic complexes of eastern Elba defined by TREVISAN (1950), major tectonic structures and the iron ore deposits. The dashed line outlines the supposed position of the Porto Azzurro pluton (BARBERI et al., 1967; DESCHAMPS et al., 1983b).

(Calamita Schists, see Fig. 1.4). These were metasomatically affected by the fluids preferably ascending along Calamita Schist-limestone contacts and through fractures in the Calamita Schists of the basement (MARINELLI, 1983). This scheme of pyrometasomatic genesis was subsequently accepted by ZUFFARDI (1990), including pre-Miocene synsedimentary iron ore deposition and remobilization, and is supported also by this work.

1.2 Aim of this work

Here, the results of field studies, ore microscopy and microprobe analysis are presented in order to clarify the interrelations between the ore generations within each deposit, and the comparison of the N-S trending ore deposits. The mineral sequence is reconstructed in detail. Zonation of minerals enable to reconstruct different precipitation and replacement phases. A second aim was to study the role of contact metamorphism with respect to the ore formation in its regional differences. The results of fluid inclusion studies and isotope analyses are presented to specify ore formation conditions.

GEOLOGICAL SETTING

1.3 Geological setting

The geological structure of Elba with its variety of nappes and rocks of both oceanic and continental environment, is formed as a consequence of the Oligo-Miocene Apenninic collisional phase (KELLER et al., 1994). After the collision, Elba was affected by polyphase extensional tectonics (KELLER & PIALLI, 1990; PERTUSATI et al., 1993; MÜHLSTRASSER & FRISCH, 1999). The classic work of TREVISAN (1950) divides the east-vergent nappe stack of Elba into 5 complexes (Fig. 1.2).

Complexes I to III are composed of Late Paleozoic to Mesozoic rocks. They belong to the continental Tuscan Unit, which represents the western margin of the Adriatic microplate. The cover sequence of the basement includes middle to upper Triassic siliciclastic-terrestrial sediments, evaporites and shallow marine carbonates. These sediments pass into a Jurassic sequence, which was deposited on a subsiding passive continental margin. Metamorphism up to greenschist facies affected parts of the Tuscan units during Late Oligocene deformation (KLIGFIELD, 1979). Complexes IV and V belong to the oceanic Ligurian Unit. Complex IV is made up of a Jurassic ophiolitic sequence and its sedimentary cover, whereas Complex V consists of rootless Cretaceous and Eocene flysch sediments. In the latest Miocene (BORSI et al., 1967; PASQUARE et al., 1983; KELLER et al., 1994), during extension in the course of the opening of the Tyrrhenian Sea, two plutons intruded into the nappe stack (SERRI et al., 1991)).

Western Elba is dominated by the granodioritic Monte Capanne pluton, dated by the U/Pb method on zircons at 6.2 ± 0.2 Ma (JUTEAU et al., 1984). In eastern Elba, a shallow quartz-monzonitic intrusion (Porto Azzurro pluton, Fig. 1.2, BARBERI et al. (1967); DESCHAMPS et al. (1983b)) is dated by the K/Ar method (whole rock) at 5.9 ± 0.5 Ma (feldspar and biotite; BORSI et al. (1967); SAUPÉ et al. (1982)). Using the Rb/Sr method (whole rock) SAUPÉ et al. (1982) dated the pluton at 5.1 ± 0.8 Ma, VENZLAFF & WALDECK (1974) at 5.4 ± 1.3 Ma. The Porto Azzurro pluton is slightly younger and as well as the Monte Capanne pluton emplaced in the upper crust and associated with top-to-the-east asymmetric extension (DANIEL & JOLIVET, 1992). Dike swarms cut through the Tuscan and Ligurian Units (BORSI & FERRARA, 1971).

Differential updoming in western Elba led to the development of a late-stage low-angle fault system and to gravitational eastward gliding of sequences in the roof of the magmatic bodies (KELLER & PIALLI, 1990). Extensive contact metamorphism occurred contemporaneously with pyrometasomatism and hydrothermal mobilization (DIMANCHE, 1969; ZUFFARDI, 1990). LIPPOLT et al. (1995) dated the late-stage paragenetic minerals adularia and hematite from the Rio Marina deposit. The Hematite samples define a $(U + Th)^{-4}$ He age of 5.39 ± 0.5 Ma and paragenetic adularia gives a mean age of 5.32 ± 0.1 Ma using the K/Ar method. Both minerals fix the end of the Elbanean iron ore mobilization and formation.

According to KELLER et al. (1994), the extensional low-angle detachment fault (Zuccale Detachment Fault; ZDF) cuts through the east vergent series in this late-stage of deformation (Fig. 1.3). Mainly N-S-striking fault systems, restricted to the eastern part of the island (BONATTI, 1965), were reactivated during this extensional event. In the calcschists of Complex II (Ortano-Rio Marina unit), a 40 Ar/ 39 Ar plateau age of 19.7 ± 0.5 Ma has been reported on muscovite (DEINO et al., 1992), possibly dating the last compressive events recorded in Elba (BRUNET et al., 2000).

Complex II and III are separated by a serpentinite-bearing overthrust zone. Prior to in-sequence thrusting and extension, the Tuscan units (Comp. I - III), were located W of unit I (Fig. 1.3). ZDF: Zuccale Detachment Fault.

1.4 Remarks on tectonics

The iron ore deposits, located in a N-S oriented belt along the east coast, are those of Ginevro, Sassi Neri, Capo Calamita, Terra Nera, Rio Marina and Rio Albano (Fig. 1.2). They occur in different rock types and tectonic positions (Fig. 1.4) of the Tuscan Complexes (TREVISAN, 1950; PANDELI & PUXEDDU, 1990; CIARAPICA & PASSERI, 1994).

The southern deposits of the Calamita peninsula are linked to the Porto Azzurro quartzmonzonite, which forms the subsurface of the Calamita peninsula (BARTHOLOMÉ & DIMANCHE (1967); BUSCH & SPOHN (1981), Fig. 1.2). The only exposure of the coarse-grained Porto Azzurro pluton is found near Serra, W of Porto Azzurro, where the originally overlying rocks shifted to NE (KELLER & PIALLI, 1990). On the SE coast, the intrusion has been detected 25 m below the surface at Stagnone (south of Sassi Neri and north of Ginevro), surrounded by autochthonous Calamita Schists, and once again towards the north in Ortano (south of Rio Marina and north of Terra Nera) 150 m below the surface (WALDECK, 1977).

The deposits of Ginevro and Sassi Neri are hosted in carbonate-bearing tectonic wedges of the Complex II (TREVISAN, 1950), surrounded by the crystalline basement (Calamita Schists). They are bound to the N-S-striking fault systems. For the Calamita Schists a SW-dipping stretching lineation can be described. The fracture tectonics fit in the E-W extension of the Tuscan area, which causes there N-S-striking horst and graben structures (DÜNKEL, 2001).

The Capo Calamita deposit can be subdivided into two tectonic units: (1) the Calamita Schists with muscovite-biotite schists and (2) the paraautochthonous carbonate-unit of probably mesozoic age, showing alpine metamorphism and late-alpine contact-metamorphic overprint. The fault breccias on the carbonate basis shows the allochthonous character of the carbonate unit. The brecciation must be younger than skarn formation, because it contains skarn fragments. An east-vergent fold structure dominates the Calamita Schists, as well as carbonates from the Capo Calamita deposit. A crenulation cleavage can be distinguished, caused by C⁴- planes cutting the main cleavage in shallow angles. The shear bands show an uniform sence of shear, according to an eastward direction of transport. At the eastern margin of the deposit, a fault with mainly deformed quartz-fragments occurs, probably representing a ductile shear zone in conjunction with brittle deformation and older than the normal faults in the central deposit.

The Terra Nera deposit tectonically rests upon the regionally-metamorphosed basement of the Calamita Schists with aplitic dikes, cut by the Zuccale Detachment Fault (ZDF). The basal contact is well exposed west of the iron ore deposit and shows a shallow, east-dipping detachment fault with a top-to-east sence of motion (SEECK, 1998). Cataclastic remnants of the Tuscan Units with sizes between several millimeters and several square meters crop out along the coast west of the deposit. On the shear plane basis an epidote-hedenbergite dislodged slice of several square meters occurs. The iron ore deposit is situated above the ZDF in highly fractured schists and quartzites of Complex III (TREVISAN, 1950). The ore formation is bound to fault zones. Metasomatism causes the precipitation of skarn minerals (hedenbergite, pistacite, garnet) in young veins and rarely in foliation planes.

A deformation (D_1) can only be observed locally and corresponds to the regional metamorphic event. D_1 can be recognized as transposed foliation (S_1) , characterized by the synkinematic growth of muscovite in the foliation plane. The structures of a second deformation (D_2) , associated with NE displacement of the units, are more pervasive. The S_2 foliation, a crenulation cleavage, is associated with pressure solution.

The tectonic history of the Rio Marina deposit is very complex. The beding planes dip NW, but the higly fractured area shows several generations of veins and normal faults, dipping ENE and indicating a W-E extension. Locally a foliation as axial plane foliation of isoclinal folds is recognized. The occurrence of magnetite decreases from bottom to top, probably not caused by tectonic deformation. Within the fractured deposit lamellar hematite formed posttectonically in young veins.

The Rio Albano deposit is mainly hosted in quarzites and schists of the Verrucano formation, Complex III, and shows magnetite veins of up to 7 cm thickness parallel the bedding of the host rock. The exploited mining area, abandon since 20 years is partly infilled or overgrown by brushwood. Also, it is not possible to identify tectonic indicators exept of the N-S oriented faults, characterizing Eastern Elba.

1.5 Different types of iron ore deposits

Three major types of ore deposits in eastern Elba can be distinguished (Fig. 1.2):

- The magnetite-bearing Calamita-type deposits are located on the Calamita Peninsula. They are associated with ilvaite-ferrosalite-ferroactinolite-grossular-epidote-skarns. The lenticular ore bodies of over 100 m length and 60 m thickness close to the (Miocene) eastern Elba intrusive body belong to the tectonic complexes I and II (Ginevro, Sassi Neri and Capo Calamita).
- The Ortano-type deposits are located in the central part of the eastern coast of Elba. They are represented by the pyrite-hematite-magnetite deposits of Rio Ortano and

Terra Nera. A meter-sized skarn body is surrounded by unskarnified cataclastite of the Zuccale Detachment Fault (Fig. 1.3) in the Terra Nera deposit.

• The Rio Marina-type includes the pyrite-hematite deposits of Rio Marina and Rio Albano. The lenticular ore bodies are hosted by Permo-Carboniferous rocks and rocks of the Verrucano Formation. These deposits are further differentiated into stratiform mineralizations in rocks of the Triassic terrestrial Verrucano Formation, hematite-pyrite masses in Carboniferous rocks and the Verrucano Formation, and in hematite veinlets related to late tectonic fractures. A sizeable skarn body is found one kilometer south of the Rio Marina deposit.

Chapter 2

Assemblages of iron ores, eastern Elba

2.1 Previous work on the Elbanean iron ore deposits

Previous work by COCCO & GARAVELLI (1954) first described Elbanean iron replacement processes; BODECHTEL (1965) and BONATTI (1965) outlined the mineral variety. Oligocene metamorphism did not exceed low grade, and thus textural features of country rocks are preserved. The distribution patterns of mineralizations, depending on the distance to the pluton, follow mainly N-S-striking fault systems, which are restricted to the eastern part of the island. DIMANCHE & RUIZ (1969); DIMANCHE (1970) and DIMANCHE (1974b) clarified the skarn assemblages from the Ginevro deposit, whereas LIPPOLT et al. (1995) looked at the paragenetic minerals of adularia and lamellar hematite (specularite). Based on field evidence and microscopic examination, several iron ore generations from the Terra Nera deposit (Fig. 1.2) are distinguished (SEECK, 1998).

The two southeastern deposits, Ginevro and Sassi Neri, are situated close to the Porto Azzurro quartzmonzonite and are dominated by magnetite (DIMANCHE, 1974b). In contrast to the other mines, they are hosted in the basement (TREVISAN, 1950) in carbonate-bearing parts of the Calamita Schists (DIMANCHE, 1971, 1974b). The ore is associated with massive skarn mineralizations containing amphiboles, hedenbergite, epidote and garnet.

The low grade (greenschist facies) overprinted crystalline basement, Calamita Schists (Complex I after TREVISAN (1950)) consists of biotite-muscovite schists, quartzite intercalations and metabasic layers (BARBERI et al., 1967; DÜNKEL, 2001). Geochemical whole rock analyses from PUXEDDU et al. (1984) distinguish the schists and quartzites as former mudstones and sandstones. The distribution of trace elements from the metabasite are similar to comparable layers from the Boccheggiano Region, Southern Tuscany (PANDELI et al., 1994); the Ti-Zr-Y values plot in the field of "Within Plate Basalts" (PUXEDDU et al., 1984). The metabasaltic layers are remarkable within the monotonous Calamita Schists. Elba is known as the most coherent region of Paleozoic outcrops in Southern Tuscany. The geochemical domains discriminated by PUXEDDU et al. (1984) show an overlap of the Calamita Schists mainly with carbonate-bearing series, and partly with phyllites of the prealpine Tuscan units (PANDELI et al., 1994). DÜNKEL (2001) assigns the Calamita-Schists on the basis of lithological and geochemical investigations as well as its carbonate-bearing cover to the Monticiano-Roccastrada unit (COSTANTINI et al., 1988). The results of BARBERI et al. (1967)

Figure 2.1: Schematic geological overview of the different lithologies of the Calamita peninsula with major tectonic structures. There are hints that the Calamita Schists can be subdivided internal into two tectono-stratigraphic units: Into the muscovite-biotite schists from the eastern part of the Calamita peninsula and into an undifferentiated basis, after BARBERI et al. (1967).

and PUXEDDU et al. (1984) imply that the Calamita Schists can be subdivided into several tectono-stratigraphical units; especially the discrimination of pre-alpine Hercynian-deformed units and alpine-deformed Paleozoic units (Fig. 2.1).

2.2 Mineral sequence and characteristics

The mineral sequence of oxide and silicate formation is complex, because of the overlap of skarn and ore formation, the complex, fast and partly contemporaneous mineral precipitation without chemical equilibria and reciprocal replacements (for details see Chapter 4). Therefore, locally observed mineral sequences described below seem to be contradictory.

The deposits (2.1.1 - 2.1.6) are listed with increasing distance to the intrusive body. The intrusive body was intersected by drill core ca. 25 m under the surface at the south-east coast of the Calamita peninsula (between Ginevro and Sassi Neri) at Stagnone. The autochthoneous deposits of Ginevro and Sassi Neri are situated closest to the pluton and do not contain hematite and only minor pyrite. Capo Calamita and Laghetto di Terra Nera show the most diversified mineral parageneses, with the pyrometasomatic formation of cassiterite and silicon-bearing magnetites (Table 2.1). In contrast to Ginevro and Sassi Neri, the deposits of Capo Calamita and Terra Nera are in tectonic contact to the underlying Calamita Schists. The deposits of Rio Marina and Rio Albano are situated further away from the intrusive body.

In this study, up to two generations of pyrite, three of magnetite and three of hematite are distinguished for Elbanean deposits. Pyrite is of minor importance in the southern deposits, whereas hematite is not present. The Capo Calamita mining district (in slightly larger distance to the intrusion) shows remnants of an old, lamellar hematite generation. The oldest preserved pyrometasomatic mineral is cassiterite, occuring in Capo Calamita and Terra Nera, whereas the deposits Rio Marina and Rio Albano show only remnants of one single magnetite generation besides predominant hematite. The northern deposits are dominated by hematite. The mineral sequences are given in Fig. 2.2. Roman numbers refer to different generations

from oldest (I) to youngest (III). The differences in stratigraphic position of the iron ore deposits are shown in Fig. 1.2 and 1.4, and briefly discussed below. The mineral parageneses depend on their distance to the plutonic body. A S-N gradient with increasing distance to the shallow underlying intrusion can be observed.

2.2.1 Miniera del Ginevro

Tourmaline-bearing aplitic dikes, cutting through the Calamita Schists, are related to the hidden east Elba intrusion. The shallow intrusion (drilled 20-30 m below the present surface, 1 km north of Ginevro) enabled the formation of tremolite in a dike and in joints in the surrounding Calamita Schists. Locally quartz-pelitic hornfels occurs. Extensive bleaching is found around clusters of quartz-veins, which penetrate the Calamita Schists in the entire area. Predominantly xenomorphic, massive magnetite is the main iron mineral, locally concentrated in centimeter thick bands parallel to the foliation of the Calamita Schists. Multiply-zoned euhedral magnetite occurs as inclusion in garnet (grossular), which was formed by contact metamorphism. Magnetite impregnated the Calamita Schists, where it shows less skarn mineralization. Dark cores and dark zones of these zoned magnetite generation (mag I, Fig. 2.3, Fig. 2.4) are preferably replaced by iron-rich amphiboles (pargasite, Fig. 2.3). Younger, unzoned magnetite (mag II) with an optically observed purple tinge (reflected light, oil immersion) has overgrown the zoned magnetite (Fig. 2.2f) and is also found as isolated aggregates in joints. The magnetite shows segmentation by brittle deformation. A second generation of Ca-Mg-rich amphiboles (tremolite, Fig. 2.4) precipitated in veins. The mineralization ceases with the late-stage hydrothermal assemblages of quartz, chlorite, adularia, minor pyrite and calcite.

2.2.2 Miniera Sassi Neri

The setting of the Miniera Sassi Neri, approx. 1.5 km north of the Ginevro deposit, is almost identical to that of the Ginevro deposit. Massive skarn mineralizations are surrounded by lowgrade metamorphic Calamita Schists. An aplitic dike, impregnated by iron ore and amphibole, is found in the western part of the Sassi Neri deposit. Like in Ginevro, relict pre-metasomatic structures or primary carbonates were not observed in the entire area. Massive magnetite is locally associated with pyrite, pyrrhotite and small crystals of epidote, adularia, sphene and quartz. Two generations of magnetite can be distinguished (Fig. 2.2e): Older euhedral, zoned and grey (reflected light, oil immersion) crystals with minor partial resorption. Magnetite of the second generation is younger than the amphibole and forms xenomorphic, unzoned crystals. This magnetite II, locally with a purple tinge (reflected light, oil immersion), encloses remnants of pyrrhotite and chalcopyrite. Pyrite is the youngest phase and of minor importance (in comparison with the northern deposits).

2.2.3 Miniera di Capo Calamita

The Capo Calamita deposit (latest exploitation 1980) is contained in tectonic slices of carbonatitic and phyllitic rocks of Triassic to Liassic age, which are in tectonic contact to the underlying Calamita Schists (DÜNKEL, 2001). This southernmost mine of Elba is made up of massive magnetite ore bodies with sharp contact to the unmineralized carbonate rock. A roughly contemporaneous polyphase garnet - ferrosalite - epidote - ferro-actinolite - ilvaite skarn (Fig. 2.8) is associated with the iron ore formation.

Figure 2.2: Mineral assemblages and sequences versus time of Elba iron ore deposits from the north (a, Rio Albano) to the south.

Figure 2.3: Multiply zoned magnetite (mag I) from the Ginevro deposit. Dark zones and cores are preferably replaced along cracks by younger, iron-rich amphibole (amph) of pargasitic composition (back-scattered electron image).

Table 2.1: Microprobe analyses (in wt%), of magnetite (mag) generations from the Capo Calamita and the Terra Nera deposit. Note the remarkable enrichment in silicon; n = number of measurements.

The Capo Calamita skarn and ore forming mineral sequence:

In general, an overlap of skarn and ore formation with two main skarn formation periods can be distinguished within the Capo Calamita deposit (Fig. 2.5):

- 1) Ferrosalite, andradite, magnetite II, ilvaite, hematite II, quartz
- 2) Pyrrhotite, ferro-actinolite, ilvaite, magnetite III, epidote, calcite, quartz

Euhedral magnetite crystals (mag II) occur in zoned andradite of the first generation. The andradite is partly replaced by younger ferro-actinolite. Ilvaite replaces ferro-actinolite and magnetite (mag III) replaces ilvaite. Magnetite veins of several centimeters in diameter crosscut the epidote skarn south of Palazzo.

Patches of malachite and azurite as alteration products of primary chalcopyrite are observed. Joints filled with iron ore and quartz occur locally. Pre-metasomatic structures are largely overprinted. Ferro-actinolite and ilvaite layers mimic primary sedimentary structures in the Capo Calamita skarn body. Few massive garnet bodies (andradite) of several tenths of square meters occur.

Three generations of magnetite, three of hematite and two of pyrite can be distinguished (Fig. 2.2d). The mineralization starts with the formation of cassiterite and pyrite. Lamellar hematite I is gradually replaced by magnetite in an unoriented mode of formation (mushketovitization). In Fig. 2.6 and Fig. 2.7 the resulting pseudomorphic mineral mushketovite (mag I) is overgrown by grey to purple (reflected light, oil immersion) magnetite margins. The silicon-bearing magnetite I generation (Table 2.1) is locally replaced by bluish maghemite (γ -Fe₂O₃). Contemporaneous to the mushketovitization, a subgeneration of magnetite I was formed as euhedral crystals. This magnetite is found as inclusions in garnet and as euhedral crystals overgrown by magnetite II. Mushketovite is also overgrown by this magnetite II. An incomplete, oriented replacement of magnetite II by hematite II along the octahedral faces

Figure 2.6: Zoned magnetite margins (mag II) overgrowing older and altered mushketovite (mag I), Capo Calamita deposit (back-scattered electron image).

follows (martitization). Minor amounts of chalcopyrite, galena and pyrrhotite are younger than hematite II and occur in joints or as inclusions in magnetite III (Fig. 2.9). The formation of magnetite III terminates the sequence of iron oxide precipitation, appearing as subtly zoned rims overgrowing older magnetite generations. Fractured euhedral crystals of pyrite II, locally with inclusions of magnetite, are bound to joints and faults and characterize the last stage of mineralization.

Silicon-bearing magnetite (Table 2.1) indicates fast precipitation at relatively high temperatures in shallow deposits (SHIMAZAKI, 1998; SHCHEKA et al., 1977), suggesting proximity of the Capo Calamita deposit to the pluton. Somewhat higher SiO₂ values of magnetite II are the result of slow thermal conductivity of the wall rocks. Proximity to the intrusive body is also confirmed by the pyrometasomatic formation of cassiterite.

2.2.4 Laghetto di Terra Nera

The three to seven meter thick cataclastic to ultracataclastic rocks of the Zuccale Detachment Fault (ZDF) separate the underlying Calamita Schists from overlying series of Complexes II and III (TREVISAN, 1950). The ore bodies are restricted to the hanging wall of the ZDF. A meter-sized skarn block is surrounded by non-skarn cataclasite of the ZDF, and therefore older than the detachment. The skarn contains epidote, hedenbergite, calcite and garnet. Also, the Calamita Schists do not show any iron mineralization. In the iron ore body, hematite and pentagon-dodecahedral pyrite crystals about 1 cm in diameter occur frequently, whereas magnetite is of minor importance. Massive granular magnetite occurs in elongated ore bodies of several square meters. The youngest iron ore generation, deformed lamellar specularite, occurs as finely dispersed crystals in a fault gouge. It appears rarely in veins of several millimeters thickness within the ZDF. Cassiterite, recognized for the first time in the Terra Nera deposit, occurs as small xenomorphic inclusions (ca. 40 μ m in diameter) in magnetite I (Fig. 2.2c, 2.10). Magnetite I occurs either in euhedral and slightly zoned crystals (mag I euhedral) or zoned in massive bodies (mag I zoned). An incomplete and unoriented martitization of magnetite (mag I to hem I) occurred contemporaneously with

Figure 2.7: Mushketovite (mag I) including relict pyrite (py I), overgrown by younger magnetite II, Capo Calamita deposit (long side 550 μ m, oil immersion).

Figure 2.8: Skarn body of the Capo Calamita deposit (Punta della Calamita), with mainly banded ferro-actinolite and black ilvaite.

Figure 2.9: Magnetite (mag II), partly oriented hematized to hem II, with chalcopyrite (cpy) and pyrrhotite (pyrr), from the Capo Calamita deposit (long side 550 μ m, oil immersion).

Figure 2.10: Early formed cassiterite in magnetite I, locally with maghemite (magh) in veins. The magnetite is overgrown by hematite margin (partly martite) and lamellar minerals of specularite (spec), Terra Nera deposit (long side 550 μ m, oil immersion).

Figure 2.11: Zoned and partly maghemized (magh) magnetite of the oldest generation (mag I) is surrounded by younger magnetite (mag II), which is replaced by recrystallized hematite (hem II), Terra Nera deposit (long side 550 μ m, oil immersion).

the formation of coarse lamellar hematite (hem I). Also bluish maghemite (Fig. 2.10, 2.11) locally pervades magnetite I. A younger, grey-purple (reflected light) magnetite generation (mag II, Fig. 2.12) with characteristic oriented martitization followed. Mushketovitization of hematite I to magnetite II occurs rarely. Zoned hematite II is formed by an incomplete, oriented martitization (lamellae after the octahedral faces) of magnetite II (Fig. 2.13), partly overgrown by fringed hematite crystals. Pyrite II and lamellar specularite (Fig. 2.10, 2.12) formed as the youngest phases. The specularite shows twinning lamination due to stress. Fine hematite crystals healed sheared crystals of the same lamellar generation. Pyrrhotite has not been detected, although it was described by BODECHTEL (1965). In contrast to Capo Calamita, magnetite III is not present.

Figure 2.12: Oriented hematitization (martite) of grey-purple magnetite (mag II) locally with bluish maghemite, besides lamellar specularite (spec), Terra Nera deposit (long side 550 μ m, oil immersion).

Figure 2.13: Remnant magnetite core in clearly zoned hematite II from the Terra Nera deposit (long side 550 μ m, oil immersion).

2.2.5 Miniera di Rio Marina

The famous specularite and pyrite crystals are mostly exploited from the Rio Marina deposit. Magnetite, chalcopyrite, sphalerite and (in young joints) adularia, quartz and rarely fluorite are observed. Remarkable skarn mineralization is found south of the mining district at the port of Rio Marina. It contains hedenbergite crystals (TANELLI & BENVENUTTI, 1998; ORLANDI & PEZZOTTA, 1996) of 20 cm in length, ilvaite, epidote, quartz, calcite and, rarely, sulfides (pyrrhotite and pyrite). The heterogeneous skarn typically occurs in rather sharp contact to the unskarnified Jurassic marble (Complex II; TREVISAN (1950)) and largely follows the sedimentary layering. Minor inclusions of pyrite I occur in magnetite I. No mushketovite and no zoned magnetite can be found all over the mining district (Fig. 2.2b). Incomplete and unoriented martitization of zoned magnetite I to hematite I occurs besides recrystallized and zoned hematite II. Skarn minerals are also extremely rare in this mining district, except for previously unknown ilvaite included in euhedral pyrite II crystals (1.5 cm in diameter). Characteristic lamellar specularite, partly bent or fractured (by brittle deformation) and with twinning lamination due to pressure, can be observed. Mineralization ceased with the latestage hydrothermal assemblages of euhedral adularia in joints, chlorite, minor calcite, and quartz.

2.2.6 Miniera di Rio Albano

The Rio Albano deposit is characterized by a single generation of magnetite (mag I) and the predominance of specularite (Fig. 2.2a). The partly euhedral and zoned magnetite crystals are preferably concentrated parallel to the foliation of the country rock (Verrucano, Complex III, TREVISAN (1950)). The magnetite is replaced (after the octahedral crystal face) by hematite I, which shows pressure twins. Unzoned and tabular specularite is the main constituent of the deposit, while late pyrite is subordinate in Rio Albano.

2.3 Summary of the regional paragenetic setting

- The six Elba iron ore deposits occur in several rock types and tectonic positions of the Tuscan units (Fig. 1.4) and can be subdivided into two groups: One containing hematite (S to N: Capo Calamita, Terra Nera, Rio Marina, Rio Albano) and the mainly hematite-free and autochthonous group of Ginevro and Sassi Neri. The latter is situated close to the Porto Azzurro quartzmonzonite.
- The deposits of Ginevro and Sassi Neri are hosted in carbonate-bearing tectonic wedges of the Complex II (TREVISAN, 1950), surrounded by the crystalline basement (Calamita Schists). Sassi Neri is not as clearly bound to the N-S striking fault system as the other deposits are (BARBERI et al. (1967); SEECK (1998); DÜNKEL (2001); ERZ (2000), Fig. 1.2), but a large NS striking fault is observed several tenths of meters west of the deposit. Moreover, relict pre-metasomatic structures are overprinted in the southern deposits (Fig. 4.3).
- The first iron oxides precipitated before or contemporaneously with skarn formation (Fig. 2.5). The mineral sequence of oxide and silicate formation shows an overlap, partly contemporaneous mineral precipitation and reciprocal replacements can be observed.

Sulfide formation starts, with py I, and completes the mineral sequence with pyrite of the second generation (Fig. 2.2).

- In general, an overlap of skarn and ore formation with two main skarn formation periods can be distinguished within the Capo Calamita deposit (Fig. 2.5, 2.8):
 - 1) Ferrosalite, andradite, magnetite II, ilvaite, hematite II, quartz
 - 2) Pyrrhotite, ferro-actinolite, ilvaite, magnetite III, epidote, calcite, quartz
- Capo Calamita and Laghetto di Terra Nera show the most diversified mineral parageneses. Three generations of magnetite, three of hematite and two of pyrite can be distinguished, with the pyrometasomatic formation of cassiterite and silicon-bearing magnetites (Fig. 2.2, Table 2.1). The pyrometasomatic sequence starts with replacement of lamellar hematite I in an unoriented mode of formation (mushketovitization), described in this study for the first time.
- The deposits of Capo Calamita and Terra Nera show remarkable enrichments in silicon. Silicon-bearing magnetites are probably the result of fast formation at relatively high temperatures in shallow deposits (SHIMAZAKI, 1998; SHCHEKA et al., 1977), suggesting proximity of the Capo Calamita and the Terra Nera deposit to the pluton.
- The occurrence of magnetite in the Rio Marina deposit decreases from bottom to top, probably not caused by tectonic deformation. Within the fractured deposit lamellar hematite formed posttectonically in young veins.
- LIPPOLT et al. (1995) dated the late-stage paragenetic minerals from the Rio Marina deposit. The Hematite samples define a (U + Th)-⁴He age of 5.39 ± 0.5 Ma and paragenetic adularia gives a mean age of 5.32 ± 0.1 Ma using the K/Ar method. Both minerals fix the end of the Elbanean iron ore mobilization and formation.
- The Rio Albano deposit is hosted in quarzites and schists of the Verrucano formation, Complex III and shows magnetite veins of up to 7 cm thickness parallel the bedding of the host rock, described in this study for the first time.
- The mineralization ceases with the late-stage hydrothermal assemblages of quartz, chlorite, adularia, minor pyrite and calcite.
- The succession of geological events is evidenced by tectonic observations (Chapter 1): After regional metamorphism (BARBERI et al., 1967) and the nappe formation causing the large N-S striking fault system, the Miocene intrusion resulted in contact metasomatism, local skarn formation and iron ore concentration. The activity of the post-intrusive ZDF in Terra Nera, during late-stage extension (KELLER et al., 1994), is postdated by the precipitation of specularite and last pyrite. Finally, all ore bodies were affected by brittle deformation due to cooling and shrinking of the igneous stock.

Chapter 3

Chemical composition

The investigations are made to restrict the formation conditions of ore and skarn deposits. The results of chemical composition of Elbanean silicates and iron oxides are presented in order to clarify the interrelations between the ore generations within each deposit, and the comparison of the N-S trending deposits.

The chemical composition of ore and gangue minerals are presented in the two subsections of silicates and oxides. Several generations of magnetite and hematite as well as pyroxene, garnet, amphibole, ilvaite, epidote, calcite, mica and adularia were analyzed using an electron microprobe. Each proportion of Fe^{2+} to Fe^{3+} is calculated stoichiometrically after the cation-correction-method. First, some methodical remarks and the basis of mineral calculation are presented.

3.1 Methods and basis of calculation

Descriptions of optical properties in this paper are based on microscopic observation under oil immersion. The six ore deposits were sampled along several profiles and 108 polished sections were examined for identification of ore minerals by optical methods with reflected light. 41 samples have been selected for electron-microprobe measurements (ca. 1880 analyses points), conducted at the Institute of Mineralogy, Petrology and Geochemistry, University of Tübingen. Chemical composition of minerals were determined using a Jeol JXA 8900 electron microprobe (EMP), equipped with three wavelength-dispersive spectrometers that are simultaneously run by the software of Microbeam Services. EMP operation conditions were 15kV accelerating voltage, $1.5 - 2.5 \ge 10^{-8}$ beam current and 20 sec measuring time. Energy dispersive system (EDS) peaks were recorded for 90 sec. The system was calibrated by the following Astimex standards (Table 3.1): Bustamite for Si (TAP) and Ca (PetJ), plagioclase for Al (TAP), olivine crystal for Mg (TAP), rhodonite for Mn (PetJ), hematite for Fe (LifH), cobaltite for Co and synthetic SrTiO₃ was used for Ti (PetJ). Matrix corrections were calculated by PRZ software supplied by Microbeams Services. The analytical error is 1% relative for the major elements. The detection limit under the specified working conditions varies between 0.04 (for Mn, Al, Ni, Ti, Mg, Si) and 0.08 wt% (for Fe, Cu, Co, Ca, Zn, Cr). Ni, Cu, Zn and Cr were below the detection limit and can be ignored. Repeated measurements of the standards between the analyses show measuring errors of up to 0.1%. The raw data were corrected automatically for background, dead time and shift of the instruments.

Each proportion of Fe^{2+} to Fe^{3+} is calculated stoichiometrically after the cation-correction-

element	standard	channel

method on the basis of perfect cation placement in the crystal lattice, the ligand field stabilization energy and weight. Every measurement point is listed and not averaged. The analyses documented in the following diagrams are completely tabulated in the Appendix.

3.1.1 General remarks

The results of the microscopic and paragenetic investigations are listed in Chapter 2. The complete data set as well as the locations of analyzed samples are shown in the Appendix. The paragenetic results were used as main criterion to select samples for electron microprobe measurements.

In the working area pyrometasomatic or hydrothermal and gradually altered minerals occur in the host rocks as well as in veins. The primary textures mostly exist as relics. In Table 3.1 the major hydrothermal minerals and their unaltered precursors are presented. Chlorite, quartz, chalcedony, calcite and epidote occur mainly in veins. Accessory zeolite, hematite, pyrite and sericite are found. Quartz and epidote, chlorite and quartz or chlorite and calcite

Figure 3.1: Classification of mica of the country rock. a) Muscovite from the Calamita Schists (C 385), surrounding Ginevro, Sassi Neri and Capo Calamita. b) Biotite from the Verrucano formation near the Rio Marina deposit (V 11).

occur in veins. In the Sassi Neri deposit veins of several centimeter thickness appear, filled with quartz at the outer rim and epidote in the center. In the Capo Calamita deposit the fluid infiltration path is shown at the transition between pure limestones and an epidote skarn with characteristic granular magnetite aggregates (ORLANDI & PEZZOTTA, 1996).

3.1.2 Hydrothermal alteration

The intensity of alteration depends on permeability and texture of the host rock. The larger the porosity, the larger the permeability is expected to be (prior to the alteration) and more intense the alteration. Both, the cleavage of the rock and tectonic fault affect the alteration. The conversion of primary mineral assemblages and the formation of new minerals results in the reduction of rock permeability. Porphyric textures show more intense alteration, micritic textures are less intense, because of less permeability.

The alteration of feldspar depends on the temperature, the activity of H_2O and on the oxygen fugacity. At low temperature for example, plagioclase preferrable alters to phyllosilicates like sericite and clay minerals. Probably at higher temperatures epidote appears around plagioclase.

3.2 Composition of silicates

The analyzed silicates, mainly formed as part of the skarn, are Ca- and Fe-rich, partly hydrous silicates as would be expected from the present setting. They are roughly sorted according to their paragenetic position (from older to younger). The analyzed oxides of the six iron ore deposits are described according to their geographic position from south to north and with respect to their distance to the underlying intrusion southeast of the Calamita peninsula (Fig.

Figure 3.2: Classification of primary feldspar of the Calamita Schists (C 385) and of late adularia in joints of the Calamita Schists (LP 1) and the Rio Marina (V 2, V 11) deposit.

Figure 3.3: Pyroxene classification from the Ginevro deposit showing a) salitic cores and rims of ferrosalitic composition (G 282, n = 34). b) Note the small element changes in the optically zoned pyroxene (G 282b) of the same ferrosalitic composition like the rims in G 282a.

1.2). Pyrometasomatically to hydrothermally formed silicates are feldspar, chlorite, epidote, ilvaite, garnet, amphiboles and allanite. Their chemical variations are described below at the assumption of pressures of ca. 1 kbar (10^8 Pa).

Fig. 3.1 and 3.2 show the composition of mica and feldspar from the crystalline basement (Calamita Schists) and feldspar from young veins from the Calamita Schists and the Rio Marina deposit. The low grade regional metamorphosed Calamita Schists contain feldspar of anorthoclase composition, while adularia occurs in youngest tectonic joints. In the Sassi Neri, Capo Calamita and Rio Marina deposits, euhedral adularia is observed in veinlets all over the deposit.

3.2.1 Pyroxene

Pyroxene $(XY[Si_2O_6])$ shows a wide range of cation substitutions:

$$XY[Si_2O_6] \qquad \begin{array}{l} X = Ca, Na, Li, Mg, Fe^{2+} \\ Y = Mg, Fe^{2+}, Fe^{3+}, Al, Ti, V, Cr \end{array}$$

A perfect placement of cations on the positions X, Y is given according to CAMERON & PAPIKE (1980). The group of monoclinic pyroxenes presented here has a wide range of chemical compositions and can be considered as members of the four component system, on the basis of 6 oxygens (after MORIMOTO (1988) and NEWBERRY (1987)):

$$CaMgSi_2O_6$$
- $CaFeSi_2O_6$ - $Mg_2Si_2O_6$ - $Fe_2Si_2O_6$

The analyzed pyroxenes vary from salite to ferrosalite and are classified after POLDERVAART & HESS (1951) as Ca-rich clinopyroxenes. Diopside and hedenbergite are particulary characteristic of contact metamorphosed calcium-rich sediments. Diopside occurs relatively early in the mineral sequence of increasing metamorphism of siliceous dolomites. All members of the diopside - hedenbergite series occur in skarns (CAMERON & PAPIKE, 1980; EINAUDI & BURT, 1982).

Figure 3.4: Classification of pyroxene: a) Salite from the country rock (Calamita Schists) surrounding the southern deposits (Ginevro, Sassi Neri and Capo Calamita) and b) Ferrosalite from the Capo Calamita deposit. Note that no zoned minerals were found within the deposit (as in Fig. 3.3).

3.2.1.1 Ginevro deposit

In the Ginevro deposit two pyroxene generations can be distinguished: Older cores of salitic composition, surrounded by ferrosalite rims (Fig. 3.3). The zoned pyroxene occurs in small xenomorphic crystals of a few millimeters in diameter. Ferrosalite can be found as rim around older salitic cores or frequently in veins crosscutting the skarn and host rock. Note the small element changes in the optically zoned pyroxene (G 282b, Fig. 3.3) of the same ferrosalitic composition like the rims in G 282a. Probably, the measured section through the pyroxene was not centric, but marginal.

3.2.1.2 Capo Calamita deposit

Salite from the Calamita Schists (crystalline basement, Fig. 3.4a) are distinct from ferrosalite of the Capo Calamita deposit (Fig. 3.4b). The ferrosalite is rarely included in unzoned garnet or occurs partly replaced by amphibole. This replacement of pyroxene to amphibole under absorption of water is described below.

It is characteristic for skarns that pyroxene only shows a small variance in chemical composition, which suggests constant chemical composition of the fluid and fast growth.

3.2.2 Amphibole

The analyzed amphiboles are all classified as Ca-amphiboles with $(Ca + Na)_Y > 1.33$ and $Na_Y < 0.67$ normalized on the basis of LEAKE et al. (1997). The amphiboles vary (depending on the X-position) from pargasite to tremolite and ferro-actinolite. Silicon ranges from 5.5 up to 8 silicon atoms per formular unit. The general formula of the monoclinic, calcium-rich

amphiboles can be expressed as

$$X = Ca, Na, K, Mn$$

$$X_{2-3}Y_5^{VI}Z_8^{IV}O_{22}(OH, F, Cl)_2 \qquad Y = Mg, Fe^{2+}, Fe^{3+}, Al, Ti, Mn, Cr, Zn$$

$$Z = Si, Al$$

Calcic amphiboles frequently show substitution of Si by Al^{IV} , which is compensated by either Al^{VI} for $(Mg, Fe)_Y$ towards tschermakite, or towards edenite depending on the $(Na, K)_X$ placement, or combined towards pargasite. Within the Mg-Fe series tremolite, actinolite and ferro-actinolite are used for the ranges of $XMg = Mg/(Mg + Fe^{2+}) = 1.0 - 0.9$, 0.9 - 0.5 and 0.5 - 0.0 respectively. The cation placement is given according to ZIMMERMANN et al. (1997). The structural formulae and the classification of the chemical analyses are made on the basis of 24 oxygens for aqueous amphiboles (attaining best cation placement) after STOUT (1972) and RICHARD & CLARKE (1990).

Amphibole can be found in Ginevro, Sassi Neri, Capo Calamita and the Rio Marina deposit. Tremolite and actinolite are essentially metamorphic minerals and characteristic for skarn formation. In thermally metamorphosed impure dolomites, tremolite forms early by reaction between dolomite and quartz. The temperature for the reaction also depends on H_2O and CO_2 concentrations (ZIMMERMANN et al., 1997).

$$5CaMg(CO_3)_2 + 8SiO_2 + H_2O \rightarrow Ca_2Mg_5Si_8O_{22}(OH)_2 + 3CaCO_3 + 7CO_2 \uparrow dolomite \qquad quartz \qquad tremolite \qquad calcite \qquad calcite \qquad dolomite \qquad$$

3.2.2.1 Ginevro deposit

In Ginevro zoned amphibole occurs (Fig. 3.5, 3.6). The cores are pargasite, while the rim and in many cases the vein amphiboles classify as tremolite (Fig. 3.7). The xenomorphic zoned amphibole rarely enclose pyroxene (DIMANCHE & RUIZ, 1969). The amphiboles of the Ginevro and Sassi Neri deposits show remarkable amounts of titanium in contrast to the other amphiboles. The parameters of Ginevro contain up to 1.4 wt% Ti, the surrounding rims and vein amphiboles include distinctly less or no titanium. The iron-rich pargasites characteristically occur in metasomatic skarns. The correlation between composition and parageneses of the calcium amphiboles is documented in Fig. 3.8 (HALLIMOND, 1943) and shows limestones as parent rocks. The tremolite (vein) and the pargasite (core) are restricted to metamorphosed impure dolomitic limestones, iron-rich pargasites are commonly associated with hydroxy- (fluorine-) metasomatism (HOLSER, 1950). The chemical composition of the Sassi Neri deposit is illustrated in Fig. 3.9, and contains Ti up to 0.32 wt %. The titanium enrichment in these two deposits indicates higher formation temperatures (RAASE, 1974) compared to other, titanium free amphiboles. Hastingsite, as described by DIMANCHE (1970) for the Ginevro deposit (three measurement points, showing more Ca and less Al in comparison to our measurements) can not be confirmed.

3.2.2.2 Capo Calamita deposit

In the Capo Calamita deposit ferro-actinolite and garnet replace one another (Fig. 3.10) in two sizeable skarn bodies (Nuova Zona and Punta della Calamita). Fractures and veins in garnet (occurring mainly in Nuova Zona and Palazzo) are filled by amphibole (ferro-actinolite).

Figure 3.5: Zoned Ca-amphiboles with pargasite cores as well as rims and veins of tremolitic composition from the Ginevro deposit; classification after LEAKE et al. (1997).

Figure 3.6: Amphibole from the Ginevro deposit besides cataclastic garnet crystals. Note the small pargasitic remnants (dark coloured) surrounded by amphibole of tremolitic composition (light), and chlorite (chl) as product of alteration (back-scattered electron image).

Figure 3.7: Zoned amphibole in veins from the Ginevro deposit. Note the core of pargasitic composition with its distinct cleavage (situated in the center), surrounded by a small, lighter tremolitic rim with imperfect cleavage (transmitted light, G 127).

Figure 3.8: Relation between composition and paragenesis of calcium amphiboles after HALLIMOND (1943). Grey: limestone as parent rock. The paragasite (NaCa₂ (Mg, Fe²⁺)₄Al₃Si₆O₂₂(OH)₂) and tremolite composition (Ca₂(Mg, Fe²⁺)₅Si₈O₂₂ (OH)₂) indicates limestones as parent rocks for Ginevro and Sassi Neri. Filled triangle: paragasite cores, open triangle: tremolite rims from the Ginevro and the Sassi Neri deposit.

Figure 3.9: Zoned Ca-amphiboles from the Sassi Neri deposit with pargasite cores and rims of tremolitic composition; classification after LEAKE et al. (1997).

Tübinger Geowiss. Arb. Reihe A, ${\bf 65}~(2002)$

Figure 3.10: Replacement of pyroxene, preferrably along cracks in garnet, to uralite of actinolitic composition from the Capo Calamita deposit (back-scattered electron image, C 303).

Needles of ferro-actinolite, up to ten centimeters long and locally radial, partly dominate the skarn body of Punta della Calamita. The chemical variance of the Capo Calamita amphibole shows 7.3 and 7.9 Si atoms per formula unit (Fig. 3.11). The amphiboles contain no measurable titanium.

Actinolite is a characteristic mineral of the greenschist facies. After BOYD (1959), the P-T stability of ferro-actinolite (at $P_{H_2O} = 1$ kbar and f_{O_2} defined by magnetite-quartz-fayalite buffer) does not exceed 480°C. At f_{O_2} higher than the magnetite-quartz-fayalite buffer, ferro-actinolite is not stable at any temperature. The main occurrence of ferro-actinolite is restricted to metamorphosed iron formations together with calcite and dolomite. Reasons are its narrow temperature range of stability, its restriction to highly reducing environments, and its chemical requirement of high Fe but absence of Na and Al (ROBINSON, 1982). In Capo Calamita pyroxene is altered to a pale green ferro-actinolite (uralite). The secondary fibrous light blue-green uralite (Fig. 3.10) is generated by a residual water-enriched magmatic fluid and reaction thereof with earlier pyroxene (KOSTYUK & SOBOLEV, 1969).

3.2.2.3 Il Porticciolo

South of Rio Marina, at Il Porticciolo, a formerly exploited skarn body was studied. The titanium free amphiboles of tremolitic composition (Fig. 3.12) occur as several centimeter long radial needles, with pyrrhotite and calcite in the interstices (Fig. 3.13). The small range of chemical composition for amphiboles from Capo Calamita and Il Porticciolo is typical for skarns.

3.2.3 Garnet

The chemical composition of garnet $(X_3Y_2[ZO_4]_3)$ is tabulated on the basis of 16 cations and 24 oxygens (DONOHUE & ESSENE, 1998) in the Appendix.

A perfect placement of cations on the positions X, Y and Z with 6, 4 and 6 cations is given

Figure 3.11: Ca-amphiboles from the Capo Calamita deposit; classification after LEAKE et al. (1997). The optically observed mineral zonation (core and rim) lies below the detection limit or is not based on element zonation.

Figure 3.12: Ca-amphiboles of tremolitic composition from the deposit Il Porticciolo, south of the Rio Marina deposit; classification after LEAKE et al. (1997).

Figure 3.13: Needles of tremolite (amph) with pyrrhotite (pyrr) and calcite (cc) in the interstices from the Il Porticciolo skarn. The pyrrhotite shows brittle deformation (reflected and transmitted light).

$$X = Mg, Fe^{2+}, Mn, Na, Ca, K$$
$$X_3Y_2[ZO_4]_3 \qquad Y = Al, Fe^{3+}, Ti$$
$$Z = Si, Fe^{3+}, Al$$

The Fe^{3+} content is calculated depending on cation distribution and placement of the X-position (modified after RYBURN et al. (1976)):

- 1. X-position is filled (X > 6)
 - Excess Fe^{2+} is converted into Fe^{3+} (on the Y-position) in order to obtain an ideal placement of X-position. This calculated Fe^{3+} is added to the Si on the tetrahedral Z-position, based on investigations of natural garnets from SCHWARTZ & BURNS (1978) and confirmed by SCHULZE (1991).

Three cases result:

- a) $(Si + Fe^{3+} < 6)$; tetrahedral position (Z) is completed with Al^{IV} up to 6
- b) $(Si + Fe^{3+} = 6)$; ideal placement of the tetrahedral position (Z)
- c) $(Si + Fe^{3+} > 6)$; excess Fe^{3+} is added up the octahedral position (Y)
- X-position is ideal (X = 6) or not filled (X < 6) No Fe³⁺ calculations are made (otherwise the X-position would subside). The tetrahedral position (Z) is filled with Al^{IV}.

SCHWARTZ & BURNS (1978) demonstrated the preferred emplacement of Fe^{3+} in the tetrahedral position in natural Fe-Ti-garnets (on the basis of crystal chemistry and Mössbauer-spectroscopy). This preferred placement of Fe^{3+} on the tetrahedral position (Z) is regarded in this study.

The garnet analyses are presented as triangle projections of the end members almandine - pyrope - grossular, classified after RICKWOOD (1968) and KOHN & SPEAR (1989) in Fig. 3.14, 3.16 and 3.17.

3.2.3.1 Ginevro deposit

Grossular occurs subordinately and exclusively in the Ginevro deposit (Fig. 3.14). Locally monomineral layers of garnet and epidote alternate, up to several centimeter thickness and parallel to the foliation of the host rock. The unzoned grossular shows XFe around 0.24 and XCa around 0.73 (XMn = 0.3, Fig. 3.14). The xenomorphic crystals of several millimeters thickness are fractured by brittle deformation (Fig. 3.6).

The optically observed multiple zonation of garnet recognized locally, have little (below detection limit) or no chemical variation (Table 3.3). Locally anisotropic garnet, which lost their cubic shape, occur. The reason can be rapid fluctuations in elemental abundance or variations in crystallizing conditions, e.g. emplacement of additional Ca-ions, of Fe^{3+} (or $(OH)^-$) in the lattice. Anisotropic garnet, preferably in grossular, can also be caused by the degree of lattice order of Al^{3+} and Fe^{3+} in octahedral places or Ca^{2+} and Fe^{2+} in dodecahedral places (ALLEN & BUSECK, 1988). Intracrystalline diffusion processes are also an explanation for the anisotropy (ANDERSON & BUCKLEY, 1973), as well as the occurrence of $(OH)^-$ -groups in the crystal lattice (ALLEN & BUSECK, 1988; MILMAN et al., 2000).

Figure 3.14: Classification of garnet after RICKWOOD (1968), samples from the Ginevro deposit. The grossular shows an average of XCa about 0.73 and XFe about 0.23, and no variation in composition.

Table 3.3: Mean and maximum values in wt% of garnet from the Capo Calamita and the Ginevro deposit. The multiple zonation (Capo Calamita: C 373, n = 32 and C 303, n = 113) is based on variable oxidation level of Fe²⁺ and the substitution of Fe²⁺ by Al³⁺. The Fe³⁺ content is calculated after RYBURN et al. (1976). Alm: almandine, and: andradite, gros: grossulare, pyp: pyrope, sps: spressartine.

Figure 3.15: Unzoned cataclastic and radius of rock-forming dimension with calcite and magnetite in the interstices, Capo Calamita deposit (back scattered electron image).

Grossular is especially characteristic of both thermally and regionally metamorphosed impure calcareous rocks, but the occurrence as a result of regional metamorphism (of impure limestone) is less common than for contact metamorphism.

3.2.3.2 Capo Calamita deposit

Figure 3.16: Classification after RICKWOOD (1968) of unzoned garnet from the Capo Calamita deposit. The andradite shows an average of XCa about 0.97 and XFe under 0.03.

In the Capo Calamita deposit unzoned andradite (Fig. 3.15, 3.16) locally dominates the skarn bodies. Subordinately, multiply-zoned andradite (Fig. 3.17) occurs. The cation variations in the chemical composition are small and non-systematic (Table 3.3), which is typical for skarn formation in a limestone host rock. Only irrelevantly more XFe (up to 0.05) and

Figure 3.17: Classification after RICKWOOD (1968) of multiply zoned garnet from the Capo Calamita deposit. The andradite shows an average of XCa about 0.97 and a variance in XFe up to 0.05.

Figure 3.18: Hypidiomorphic, multiply zoned andradite, from the Capo Calamita deposit, which is partly replaced by ferro-actinolite, besides small magnetite crystals (back scattered electron image).

changing Fe and Al^{3+} contents were observed. Impure limestones as host rock and relatively fast formation from a fluid with constant chemical composition causes the characteristic crystallisation of such pure andradite.

Fig. 3.18 shows hypidiomorphic, multiply-zoned andradite, which is partly replaced by ferroactinolite, besides small magnetite crystals. For this small differences in the zonation of the garnet crystals, the following reasons could apply (ANDERSON & BUCKLEY, 1973): The chemical composition of the whole rock affects Ca-content of the analyzed garnets. A surplus of Ca expresses the grossular component of garnets (Ca > 1 per formula unit), besides Ca-hornblende. In the majority of the polished sections analysed in this study, garnet is retrogradely replaced by chlorite. By comparison to garnet, chlorite has a higher Mg-content, which results in decreasing Mg concentration towards the garnet rim.

And radite typically occurs in contact metamorphosed impure calcareous rocks and skarn deposits. This involves the participation of $Fe_2O_3 \pm SiO_2$:

$$\begin{array}{rclcrcl} 3CaCO_3 &+& Fe_2O_3 &+& 3SiO_2 &\rightarrow & Ca_3Fe_2Si_3O_{12} &+& 3CO_2 \uparrow\\ calcite & hematite & quartz & and radite \end{array}$$

If FeO is also introduced, hedenbergite forms in addition to andradite and magnetite as the characteristic skarn assemblage. If $SiO_2 : Fe_2O_3 > 3$, wollastonite and andradite may be produced, but the ratio of $SiO_2 : Fe_2O_3$ in the Elbanean skarns did not exceed 3 and wollastonite is not observed. Nevertheless, the frequent retrograde alteration possibly erased former mineral generations. Besides andradite, magnetite of the second generation (Chapter II) precipitated.

$$\begin{array}{c} 2Fe_2O_3 + 4CaCO_3 + 2Fe_{aq}^{2+} + 5H_4SiO_4 \rightarrow \\ hematite \\ calcite \\ Ca_3Fe_2Si_3O_{12} + CaFe(Si_2O_6) + Fe_3O_4 \\ and radite \\ hedenbergite \\ \end{array} + 4CO_2 \uparrow + 8H_2 + 4H^+ \\ \end{array}$$

3.2.4 Ilvaite

Table 3.4: Chemical composition of ilvaite from Rio Marina (R. M.) and the Capo Calamita (C. C.) deposit, as well as measurements from Beran (1980) and Carrozini (1994) from the Rio Marina skarn (R. M. skarn), n.d. = no data. The proportion of Fe^{2+} to Fe^{3+} is stoichiometrically calculated after DROOP (1987) and STRUNZ (1966).

The iron-rich water-bearing silicate ilvaite (lat. Ilva = Elba) with the formula

$$CaFe_{2}^{2+}Fe^{3+}[OH|O|Si_{2}O_{7}]$$

after STRUNZ (1966) is typical of calc-silicate rocks. Ca can be substituted by Mg up to 4.5 % (DIETRICH, 1972a) and by Mn up to 13.5 % (PLIMER & ASHLEY, 1978), and Fe³⁺ (1 %) can be substituted by aluminium and silicon. The proportion of Fe²⁺ to Fe³⁺ is stoichiometrically calculated on the basis of 6 cations and 9 oxygens (after DROOP (1987); STRUNZ (1966)). The main occurrence of ilvaite is restricted to pyrometamorphism with silicon supply (KRÄUT-NER & MEDESAN, 1969), autometasomatism of impure carbonates or to hydrothermal pyroxene or magnetite alteration. Within skarn bodies, ilvaite occurs preferably in the iron-rich horizons, after the formation of amphiboles. Replacement of clinopyroxene by hydrothermal fluids causes ilvaite and later calcite precipitation (VLAD & VASILIU, 1969). The stability of ilvaite depends mainly on the oxygen fugacity (BURT, 1971b; LUCCHETTI, 1989). The crystallization of ilvaite ranges from 90°C (KHETCHIKOV et al., 1968) up to 470 \pm 25°C (GUSTAFSON, 1974).

$$\begin{array}{c} 6Ca_{2}Fe_{5}Si_{8}O_{2}(OH)_{2} + 2H_{2}O + 4H^{+} \rightarrow \\ Ca-amphibole \\ 10CaFe_{2}^{2+}Fe_{3}^{3+}(OH|O|Si_{2}O_{7}) + 28SiO_{2} + 2Ca_{aq}^{2+} + 5H_{2} \\ ilvaite \\ quartz \end{array}$$

This reaction produces quartz, which appears in the parageneses, together with calcite in interstices. The analyzed ilvaite originate from Capo Calamita and Rio Marina deposits (Table 4.6). Ilvaite crystals up to 20 centimeter in length can be locally found in the Punta della Calamita skarn body. Smaller sized crystals of several millimeters also occur in the other skarnified areas of the deposit. In the Rio Marina deposit, skarn minerals are extremely rare, apart from previously unknown ilvaite included in euhedral pyrite crystals. South of the deposit, at the Torre di Rio Marina, skarnified marble with an ilvaite dominated zone of several square meters occur. This nearly pure ilvaite zone (ca. 100 m south of the Torre di Rio Marina) shows orthorhombic ilvaite crystals (CARROZZINI, 1994) as "quenched" metastable phase (CARROZZINI, 1994), because ilvaite shows a monoclinic structure under normal conditions.

Rare xenomorphic ilvaite remnants occur in the Ginevro deposit included in or replaced by magnetite. BARTHOLOMÉ & DIMANCHE (1967) described the following equilibrium for Elbanean deposits:

$$\begin{array}{c} 11CaFe(Si_{2}O_{6}) + 5Fe_{3}O_{4} + 1/2H_{2}O \rightarrow \\ & hedenbergite \end{array} \\ 8CaFe_{3}(Si_{2}O_{7})O(OH) + Ca_{3}Fe_{2}(SiO_{4})_{3} + 3SiO_{2} \\ & ilvaite \end{array}$$

For high total pressure, higher water fugacity and lower temperature, the following reaction results in the formation of ilvaite and hematite:

$$\begin{array}{ccc} 2Ca_{3}Fe_{2}(SiO_{4})_{3} + \underbrace{12Fe_{3}O_{4}}_{magnetite} + \underbrace{6SiO_{2}}_{quartz} + \underbrace{3H_{2}O}_{quartz} \rightarrow \underbrace{6CaFe_{3}(Si_{2}O_{7})O(OH)}_{ilvaite} + \underbrace{11Fe_{2}O_{3}}_{hematite} + \underbrace{11Fe_{2}O_{3}}_{hematite} + \underbrace{11Fe_{2}O_{3}}_{llvaite} + \underbrace{$$

The paragenesis ilvaite + hematite does not occur - neither in Ginevro nor in the Capo Calamita deposit. But the replacement of ilvaite by magnetite and vice versa appears (see below in Chapter 4, Fig. 4.5). Calcite minerals occur apart from ilvaite, replacing pyroxene (VLAD & VASILIU, 1969):

$$\begin{array}{c} 6CaFeSi_{2}O_{6}+(H_{2}O+CO_{2}+7/2O_{2})\rightarrow\\ &\\ 2CaFe_{2}^{2+}Fe^{3+}[OH|O|Si_{2}O_{7}]+4CaCO_{3}+8SiO_{2}\\ &\\ &\\ ilvaite\end{array}$$

The chemical composition of ilvaite from the Capo Calamita deposit, the Rio Marina deposit and the Torre di Rio Marina skarn is uniform (Table 4.6).

The dehydration curve of ilvaite coincides with that of ferro-actinolite (BARTHOLOMÉ & DIMANCHE, 1967), resulting in the upper limit to the temperature of formation for ilvaite: 430°C at 0.5 kbar, 460°C at 1 kbar (ERNST, 1966). The reaction can be described as:

$$\begin{array}{c} 3Fe_{3}O_{4} + Ca_{2}Fe_{5}(Si_{8}O_{22})(OH)_{2} + 4CaFe(Si_{2}O_{6}) + 2H_{2}O \rightarrow \\ magnetite & ferro-actinolithe & hedenbergite \end{array}$$

$$\begin{array}{c} 6CaFe_3(Si_2O_7)O(OH) + 4SiO_2\\ ilvaite \qquad quartz \end{array}$$

3.2.5 Epidote

Table 3.5: Mean values of epidote from the Capo Calamita (C 103, n = 8) and the Ginevro deposit (G 282; n = 2). Note the small chemical differences between the deposits.

Epidote is a typical product of contact metamorphism. The composition of the epidote group can be expressed by the formula:

$$Ca_2Al_2O(Fe^{3+}, Al)OH[Si_2O_7][SiO_4].$$

Tübinger Geowiss. Arb. Reihe A, 65 (2002)

42

 Fe^{3+} content is calculated depending on the change in the cation distribution on the basis of 12.5 oxygens (modified after RYBURN et al. (1976)).

In Ginevro epidote is associated with clinopyroxene, Ca-amphibole, garnet and chlorite. In Sassi Neri and Ginevro, unzoned epidote is found along bleached zones with quartz-bearing margins and epidote in the center. Epidote, a common mineral in skarns occurs in a wide variety, analysed exemplarily for the two locations east of Capo Calamita and in the Ginevro deposit (Table 3.5). Note the differences in Ca-, Mg-, Al- and Ti-content of epidote between the locations. Epidote of the Ginevro deposit or skarn is characterized by higher Si, Mg and K content. Epidote from Calamita Schists, east of the Capo Calamita deposit, shows higher contents of Al and Ca (Table 3.5).

Previously unknown was the occurrence of small crystals of monoclinic-prismatic allanite, which is rare but widely scattered in the skarn from the Ginevro deposit. Allanite is a characteristic accessory mineral in many granodiorites, in limestone skarns and pegmatites. The structure of allanite is essentially the same as that of other members of the epidote group. The chemical composition of allanite from the Ginevro deposit is presented in Table 3.6.

3.3 Results from chemical composition of silicates

- Different types of deposits are distinguished, according to the chemical composition: in Ginevro and Sassi Neri, amphibole dominated lenses with minor pyroxene and garnet occur. In the Capo Calamita and the Rio Marina deposits extensive skarn bodies appear. A skarn slice in the Zuccale Detachment Fault is exposed in the Terra Nera deposit. In the deposit of Rio Albano, no skarn is found.
- The analyzed silicates, mainly formed as part of the skarn are expectedly Ca- and Fe-rich and hydroxyl-bearing silicates. Thus, a Fe- and Ca-rich composition is estimated for the fluid influx. The metasomatic minerals did not grow under isochemical conditions, as is to be expected for skarn formation processes. The different silicates are mostly uniform for all analyzed skarn bodies, contrary to the expectations and indicating a constant, fluid dominated formation system.
- Two generations of pyroxenes are variably enriched in Fe and no hedenbergite occurs, but it has been mentioned in the literature (DIMANCHE & RUIZ, 1969). The salite-cores from Ginevro have a similar composition as pyroxene in the surrounding Calamita Schists. Ferrosalite from Ginevro overgrew pyroxene of salitic composition. The analyzed ferrosalite shows minor variance in chemical composition with FeSiO₃ below 90%, which is characteristic for skarns and suggests constant chemical composition of the fluid and fast growth.
- In the Capo Calamita deposit only pyroxene of ferrosalitic composition can be found, which is altered to amphibole (uralite) and garnet, presumably by water-rich fluids (KOSTYUK & SOBOLEV, 1969). The temperature of uralite (actinolite) formation from the Capo Calamita deposit did not exceed 480°C (at $P_{H_2O} = 1$ kbar, after BOYD (1959)). The main occurrence of ferro-actinolite, a characteristic mineral of the greenschist facies, is restricted to metamorphosed iron formations together with calcite and dolomite (ROBINSON, 1982).
- The pargasite cores of Ginevro and Sassi Neri show remarkable amounts of titanium, which are characteristic for metasomatic skarns and may indicate higher pyrometasomatic formation temperatures than those for the other Elbanean deposits (RAASE, 1974).
- Tremolite (Ginevro, Sassi Neri and Il Porticciolo) and pargasite (Ginevro, Sassi Neri) are restricted to metamorphosed impure dolomitic limestone (HALLIMOND, 1943), iron-rich pargasites are commonly associated with hydroxy- (fluorine-) metasomatism (HOLSER, 1950). The skarns formed from impure limestone have the following mineral sequence:

$$pyroxene \rightarrow garnet \rightarrow amphibole \rightarrow ilvaite \rightarrow epidote \rightarrow adularia$$

• There are only small differences in the chemical composition of the two different garnets: In the Capo Calamita deposit "pure" and radite (containing $X_{\rm Ca} > 93~{\rm wt\%}$) occurs, while in the Ginevro deposit grossular (containing $X_{\rm Fe} = 72~{\rm wt\%}$ and $X_{\rm Ca} = 23~{\rm wt\%}$) can be found. The optically observed multiple zonation of garnet recognized locally, has little (below detection limit) or no chemical variation.

- If $SiO_2 : Fe_2O_3 > 3$, wollastonite and andradite may be produced, but the ratio of $SiO_2 : Fe_2O_3$ in the Elbanean skarns did not exceed 3 and wollastonite is not observed (EINAUDI et al., 1981; HARRIS & EINAUDI, 1982).
- The chemical composition of ilvaite is uniform in the deposits of Capo Calamita, Rio Marina, and the Torre di Rio Marina. The dehydration curve of ilvaite coincides with that of ferro-actinolite (BARTHOLOMÉ & DIMANCHE, 1967), resulting in the upper limit to the temperature of formation for ilvaite: 430°C at 0.5 kbar, 460°C at 1 kbar (ERNST, 1966).
- Previously unknown allanite crystals were described, a typical accessory component in granodiorites, limestone skarns and pegmatites. The occurrence of adularia in all deposits indicates late-stage formation from a potassium rich fluid in veins, syngenetic with pyrite.

3.4 Composition of oxides

Results of the chemical composition of Elbanean iron oxides are presented in order to clarify the interrelations between the ore generations within each deposit and the comparison of the N-S trending deposits. The analyses, especially of the zoned minerals may help to reconstruct different precipitation and replacement phases.

Magnetite

Spinel group :
$$A_8^{[4]}B_{16}^{[6]}O_{32}$$

normal spinel: $R_8^{2+}R_{16}^{3+}O_{32}$ $R^{2+} = Fe, Mg, Mn, Zn, Ni, Cu$
inverse spinel: $R_8^{3+}(R_8^{2+}R_8^{3+})_{16}O_{32}$ $R^{3+} = Fe, Cr, Co, Al, V, Ge, (Fe + Ti)$

Magnetite Fe_3O_4 , where 2/3 of all Fe^{2+} ions are substituted by R^{3+} , is the most resistant iron oxide (HOLLEMAN & WIBERG, 1995). Because of its atomic radius, the ion radius and the ligand stabilization field energy, cobalt behaves similar to chromium in the spinel lattice. Hence, low spin Co^{3+} prefers, due to its charge and stabilization energy, the octahedral position (substituting for Fe^{3+} ; HOLLEMAN & WIBERG (1995)).

The determination of the Fe^{2+}/Fe^{3+} ratio and the correction of iron positioning in spinel $(X^{II}Y_2^{III}O_4)$: The proportion of Fe^{2+} to Fe^{3+} is calculated stoichiometrically according to the cation-correction-method on the basis of three cations and four oxygens (DROOP, 1987). This assumes a perfect placement of cations on the positions X and Y as a function of their cation change, ligand field stabilization energy and weight.

Hematite

Trigonal Fe_2O_3 contains almost pure Fe^{3+} , rarely small amounts of trace elements as Al, Ti or Si occur. The placement of cations on each position is completely listed in the Appendix.

The discrimination of the oxide generations by their chemical composition is documented in Table 3.7 (for detailed analyses, see the Appendix). The oxides can be subdivided into several generations, as described in Chapter 2 (parageneses), and deduced from the textural

Figure 3.19: Needles of mushketovite surrounded by subtly zoned younger magnetite from the Capo Calamita deposit (back scattered electron image). The element variations of the marked profile line is presented in Fig. 3.20.

results described below. The northern deposits are dominated by hematite, whereas the deposits of Ginevro, Sassi Neri and Capo Calamita are dominated by magnetite.

3.4.1 Miniera del Ginevro

Strong variations in light element contents (silicon, aluminum, calcium and magnesium) are typical for the Ginevro magnetites, in which the TiO_2 contents are high: The older magnetite (mag I) shows enrichment in SiO₂ up to 5.2 wt% and in Al₂O₃ of max. 2 wt%. The concentration of trace elements decreases from core to rim (Table 3.7). Both, core and rim show relatively high TiO₂ contents (up to 0.6 wt%). The younger, light magnetite (mag II) shows no remarkable enrichments except for MgO (Table 3.7).

3.4.2 Miniera Sassi Neri

The setting of the Sassi Neri deposit is identical with that of the Ginevro deposit. Only the aluminum content shows remarkable variations and increasing proportions: The euhedral, older magnetite generation (mag I) can be distinguished from a second, younger generation (mag II). The MgO content of magnetite I (overgrown by amphibole) is relatively high compared to other magnetites with values up to 0.4 wt% (mean 0.1 wt%). Both generations show high Al₂O₃ contents, the older generation up to 2.2 wt% (mean 0.85 wt%). The younger magnetite (mag II) reveals Al₂O₃ contents up to 3.1 wt% (mean 1.1 wt%) and slightly increasing SiO₂ contents (Table3.7).

3.4.3 Miniera di Capo Calamita

The variation of the ore mineralizations is conspicuous. Characteristic is the occurrence of mushketovite (Fig. 3.19, 3.20). Cobalt-bearing magnetites are also described here for the first time.

Table 3.9: Oxide concentration of magnetite subgenerations from the Terra Nera deposit. Presented are mean and maximum values in wt%.

The deposit shows the clearest distinction of paragenetic stages. Three generations of magnetite and two of hematite can be distinguished. Lamellar hematite (hem I) is gradually replaced by magnetite in an unoriented mode of formation (Chapter 2, mushketovitization, Fig. 3.19). The generated mushketovite (mag I, Fig. 3.20) has constant amounts of cobalt (up to 0.14 wt%) and minor SiO₂ contents (Table 3.8) in Vallone Basso. The euhedral magnetite generation (mag I euhedr., Fig. 3.21) contains no cobalt and shows SiO₂ contents of up to 3.5 wt%. Younger magnetite margins (mag II, Fig. 3.22) surrounding magnetite I have high SiO₂ contents up to 4.9 wt% and a subtle variance in CaO and MgO. The margins overgrowing the cobalt-bearing mushketovite (Vallone Basso) contain also CoO of max. 0.2 wt% (Table 3.8). Magnetite III is enriched in SiO₂. Other elements are not significant or below detection limits (Table 3.7). Lamellar hematite (hem I) of Capo Calamita contains high amounts of SiO₂, younger hematite (hem II) is enriched in SiO₂ and Al₂O₃ (Table 3.7, Fig. 3.23).

Cobalt occurs without exception in mushketovite and the rim around Co-bearing mushketovite (because of nucleation). Around euhedral, Co free magnetite no cobalt-bearing rims can be found.

3.4.4 Miniera Laghetto di Terra Nera

Specularite shows relatively high TiO_2 content by comparison to other examined deposits: Hematite occurs frequently, whereas magnetite is of minor importance. The zonation of magnetite (mag I) is based on variations in silicon and carbon. Cores of magnetite I can be distinguished by high SiO₂ concentration up to 3.0 wt% and MgO contents of max. 0.4 wt% (Table 3.9). The magnetite margin (mag I, margin) contains minor amounts of trace elements. Magnetite of the second generation (mag II) shows a relatively high TiO₂ concentration (max. 0.2 wt%) and minor SiO₂ content (Table 3.9, Fig. 3.24). Unzoned hematite

Figure 3.24: Oxide concentration of the Terra Nera iron oxides in their mineral forming sequence. The high value of SiO_2 of the magnetite I cores (mean 2.0 wt%) are listed in Table 3.9.

Figure 3.25: Hematite pseudomorph with relict magnetite besides lamellar specularite from the Terra Nera deposit (ES 42, long side 550 μ m).

Figure 3.26: Partly ductile deformed as well as broken lamellar specularite between magnetite crystals from the Terra Nera deposit (long side 1100 μ m).

Figure 3.27: Remnants of magnetite in hematite besides lamellar specularite from the Rio Marina deposit (V 14, back scattered electron image).

(hem I, Fig. 3.25), produced by martitization of older magnetite, does not reveal remarkable enrichment of trace elements, whereas zoned hematite (hem II) varies in Al₂O₃ and SiO₂. Specularite (hem III, Fig. 3.26) of the Terra Nera deposit is characterized by a relatively high Al₂O₃ content (Fig. 3.24) and shows high TiO₂ concentration (up to 0.6 wt%). Silicon-bearing magnetites (per definition SiO₂ > 1wt%, SHCHEKA et al. (1977)) occur only in the higher tempered magnetite generations of Terra Nera. SHIMAZAKI (1998) showed that silicon-bearing magnetites are rapidly precipitated, as Si is otherwise incongruous in magnetite. Silicon occupies the tetrahedral position of the crystal lattice, compensated by Fe²⁺ in the octahedral position. The silicon enrichment is formed under rapid cooling conditions in a Si-oversaturated fluid system, assisted by silicon from the surrounding host rocks.

3.4.5 Miniera di Rio Marina

One generation of magnetite but no mushketovite occurs in the deposit Rio Marina. Magnetite (mag I) has little enrichment in SiO₂ (max. 0.9 wt%). Rarely, zoned hematite (hem I), partly with relict magnetite (Fig. 3.27), varies in contents of SiO₂, MgO and Al₂O₃. Nearly pure specularite (hem II) shows the highest amounts of Al₂O₃ (mean 0.6 wt%, Table 3.10).

3.4.6 Miniera di Rio Albano

Tabular specularite is the dominant phase in the northernmost deposit, whereas magnetite is minor. Both magnetite I, which is replaced oriented by hem I, and hematite I have no remarkable enrichments. Locally, subtly and multiply-zoned hematite I (Fig. 3.28), observed optically, does not have significant chemical zonation. Specularite (hem II) has little enrichment in Al_2O_3 (Table 3.11).

3.5 Results from chemical composition of oxides

Only small element variations were found within the iron oxides. The differences in chemical composition of the iron ore deposits are an expression of different host rocks. Optical observed zonation of the oxides have no significant chemical variation. The absence of common magmatic diversity speaks in favour of secondarily mobilized and replaced Fe.

- The mineralogical variety of assemblages reflects the alternating crystallization of minerals under conditions of variable oxygen and sulfide fugacity (e.g. magnetite - hematite replacement). The crystallization of magnetite depends mainly on the redox-potential. Under contact-metamorphic conditions magnetite precipitates at higher temperatures and lower oxygen partial pressure than hematite (SHI, 1992).
- Small differences in trace element contents within the deposits are probably caused by different host rocks: Ginevro and Sassi Neri are characterized by high amounts of (hardly removable) aluminium, probably derived from the surrounding, aluminiumbearing Calamita Schists.
- Silicon-bearing magnetites (SHCHEKA et al., 1977) occur only in the higher tempered, old magnetite generations of Ginevro, Capo Calamita and Terra Nera, as well as in hematite I of the Capo Calamita deposit. The silicon enrichment of Ginevro, Capo Calamita and Terra Nera is formed under rapid cooling conditions in a Si-oversaturated fluid system, assisted by silicon from the surrounding host rocks, as generally described by SHIMAZAKI (1998).

Magnetite in Sassi Neri does not contain silicon, presumably because of slower precipitation and more equilibration between the fluid and the mineral phase.

- Small amounts of malachite and azurite, possibly of the Co-bearing modification kolwezite (Cu, Co)₂(CO₃)(OH)₂, and Co-bearing magnetite are restricted to the western flank of the Capo Calamita deposit. Cobalt occurs without exception in mushketovite and the rim around Co-bearing mushketovite (because of nucleation). Around euhedral, Co free magnetite no cobalt-bearing rims can be found. After the local precipitation of cobalt, the fluid contains no more cobalt.
- The remarkable S-N gradient is documented in the multitude of mineral assemblages and replacements in the south (Capo Calamita and Terra Nera) and the decrease with increasing distance to the shallow intrusion towards the north (Rio Albano).
- The magnetite in the northern deposits of Rio Marina and Rio Albano, as well as the youngest generation in Terra Nera are pure iron oxides and consequently of lower temperature origin. The decrease towards the north, towards younger oxide generations and lower content of impurities indicates two different types of iron ore deposits: The deposits of Ginevro and Sassi Neri and the (hematite-bearing) deposits of Capo Calamita, Terra Nera, Rio Marina, and Rio Albano towards the north.
- Under epizonal conditions hematite (specularite) occurs as sparry needles, whereas mesozonal hematite preferably appears as isometric, thick lenticular crystals without (0001) faces in granoblastic fabric (e.g., hem I from the Rio Marina deposit or hem II from Terra Nera). The specularite from the Terra Nera deposit has a slight enhancement in titanium concentration in the margins. Only specularite of the Rio Marino deposit shows a mean of 0,6 wt% Al₂O₃.

Chapter 4

Skarn deposits

Clarifying the genesis of Elbanean iron ore deposits requires the investigation of skarn bodies. Skarn formation includes a wide range of potential ore-forming environments. Most geochemical studies of iron ore and skarn deposits have focused on mineral phase equilibria, fluid inclusions and isotopic investigations of fluid sources and pathways, which are essential to enlighten the ore forming processes.

4.1 Definition of skarns and skarn deposits

Skarns are formed during regional or contact metamorphism. A variety of metasomatic processes involves fluids of magmatic, metamorphic, meteoric or marine origin. Skarns are associated with different environments such as plutons, major shear zones, geothermal systems, on the seafloor and lower crustal depths in metamorphic terrains (MEINERT, 1983).

EINAUDI et al. (1981) suggests to use the term "skarn" strictly in a descriptive sense, without genetic interpretation. In general, skarns can be subdivided into endo- and exoskarns. Problems in determination of the skarn topology due to the irregular shape of the intrusive body arise, when the contact is not exposed. EINAUDI et al. (1981) defined skarn according to its mineralogy, which includes (a wide variety of) calc-silicate minerals and is usually dominated by pyroxene and garnet. Commonly, there is a zonation pattern of the exoskarn, dominated by proximal garnet, whereas the distal skarn contains more pyroxene (Fig. 4.1). Minerals for skarn classification are garnet, pyroxene and amphibole, which occur in all skarn types and show a wide compositional variability (Chapter 2).

In most cases, fluid transfer and fluid composition control the skarn and ore deposition (MEIN-ERT, 1992). The host rock affects the composition and texture of the skarn bodies, and the skarn and ore minerals often result from the same hydrothermal system.

Skarn bodies are rarely formed by metamorphism of pre-existing ore deposits, e.g. in Aguilar in Argentina (GEMMELL, 1992) or the Franklin Furnace, USA (JOHNSON et al., 1990). Most of the skarn deposits are related to igneous activity and have been described by ZHARIKOV (1970a,b); SHIMAZAKI (1980); EINAUDI et al. (1981); MEINERT (1983); NEWBERRY (1987) and MEINERT (1992). ZHARIKOV (1970a,b) was the first to describe systematic variations in skarn mineralogy among major skarn classes, using phase equilibria, mineral compatibilities and compositional variations in solid solution series. EINAUDI et al. (1981) and BURT (1982) classified deposit types and their mineralogical variations.

Figure 4.1: Zonation of classic skarns depending on geometry of the pluton and the fluid flow. The proximal exoskarn is dominated by garnet and the distal skarn contains more pyroxene. The complete legend is listed in Fig. 4.2 (after MEINERT, 1992).

4.2 Formation of skarn deposits; general trends

The formation of a skarn deposit as dynamic process was first described by LINDGREN (1902); BARRELL (1907) and GOLDSCHMIDT (1911). Contact metamorphism is complex and not a simple isochemical recrystallization process, because of the strong temperature gradients and fluid circulation (SALEMINK & SCHUILING, 1987; BOWERS, 1990). There is often a transition from early metamorphism resulting in hornfels and reaction skarn to later (proximal) metasomatism resulting in coarse-grained ore-bearing skarn (Fig. 4.2).

The level of intrusion as well as the depth of formation are also largely a function of the surrounding wall rock temperature. Assuming an average geothermal gradient for an orogenic area of 35°C per kilometer (BLACKWELL et al., 1990), the volume of rock affected by temperatures in the range of 400°-700°C would be considerably larger surrounding a deeper pluton than a shallower one. Metamorphism is more extensive and higher tempered at depth than at the top of the system (MEINERT, 1992). The depth of skarn formation also affects the mechanical properties of the host rock. In a deep skarn environment, rocks tend to deform in a ductile manner rather than by brittle fracturing. Host rocks at shallow depths mainly deform by fracturing and faulting (rather than folding). In shallow skarn deposits, intrusive contacts are sharply discordant to bedding, caused by the pressure relief (EINAUDI & BURT, 1982).

While cooling, the intrusion is affected by shrinking brecciation, causing intense fracturing of the plutonic body as well as of the surrounding rocks (MEINERT, 1983). As a consequence of the associated increase in rock permeabilities, intensive metasomatic-hydrothermal activity along the transport channels starts. This results in dissolution of material, leaching of the

Figure 4.2: Evolutionary stages of pluton-associated skarn deposits: a) Initial intrusion causes metamorphism of sedimentary rocks. b) Metamorphic recrystallization and phase changes reflect protolith composition. Diverse calc-silicate minerals were formed by fluid circulation in impure lithologies and along fluid boundaries. c) Crystallization and dissolution of an aqueous phase result in fluid-controlled metasomatic skarn. d) Cooling of the pluton and the circulation of meteoric water causes (mainly in shallow zones) retrograde alteration of metamorphic and metasomatic minerals (after MEINERT, 1992).

mafic components of the surrounding rocks and the redeposition of the dissolved material together with that of the fluid influx.

Skarn bodies crosscut through bedding and replace primary structures. Strong hydrofracturing associated with shallow-level intrusions increases the permeability of the host rocks, not only for igneous-related metasomatic fluids, but also for later, meteoric fluids (SHELTON, 1983). Retrograde skarn minerals (epidote, amphibole, chlorite, and other hydrous phases) overprint the prograde mineralization. The inflow of meteoric water and retrograde alteration of skarn minerals is more intensive and more pervasive in shallow skarn systems (Fig. 4.2; EINAUDI & BURT, 1982). The shallowest and youngest known skarns are forming in active geothermal systems, e.g. the Tuscan Larderello-Tavale geothermal field (CAVARRETTA et al., 1982).

Pure limestones rarely show contact metamorphic silicates, but they are capable to react with fluids and assimilate gas containing metal elements. Volatile components leak into veins and dislocation planes or other permeable locations of the wall rock. The pressure relief leads to vaporization, distillation and reaction with the wall rock and causes metal formation in the contact aureole.

Under pneumatolytic conditions, limestone decomposes because of high contents of dissolved H_2S in the fluid. CaCl₂ resolved from the limestone migrates away as dissolved brine or reacts with the silicates of the wall rock. Tourmaline and topaz formation is not typical in limestones, but pneumatolytic silicate replacements are characteristic.

The formation of minerals depends on temperature, pressure, the element concentration, modification of ionic concentration of H (pH) and the redox potential (Eh).

Under epithermal conditions the fluid shows concentrated, poorly dissociated, alkali- and chlorine-rich electrolytic solutions. The metal dissolves as alkali- or polysulfides (DIPPLE & GERDES, 1998; MEINERT, 1987). With increasing distance to the intrusive body, recrystal-lization vanishes.

4.3 Skarn deposits of eastern Elba

On Elba island, the shallow intrusion of a granodiorite - quartzmonzonite pluton into a series of previously regionally metamorphosed gneisses, marbles and marble-bearing schists produced extensive deposits of Ca-Fe skarns and iron ores. Structural and petrological investigations show that the contact metamorphic aureole was formed as a result of thermal heating accompanying fluid convection (SEECK, 1998; ERZ, 2000; DÜNKEL, 2001).

EINAUDI et al. (1981) described the difficulty to distinguish skarn zonation without an outcrop of the plutonic contact zone. Elba skarns suffer similar problems, separating the overlapping and partly altered or replaced mineral assemblages. The Elbanean skarn bodies are classified by EINAUDI et al. (1981) as contact pneumatolytic replacement deposits. The exoskarn is altered by circulating fluids. Supercritical gas discharge due to pressure relief caused both vaporization and distillation processes in the wall rock (EINAUDI et al., 1981).

The shallow East Elba pluton with temperatures not exceeding 650°C (at the contact aureole of the intrusive body and in the surrounding wall rocks, DIMANCHE (1971)) enabled the formation of wollastonite only in the inner contact zone. The mineral sequence of oxide and silicate formation is apparently inconsistent, because of the overlap of skarn and ore formation, the complex, fast and partly contemporaneous mineral formation without chemical equilibria, and reciprocal replacements (Chapter 2).

Figure 4.3: Ductily deformed Calamita Schists surrounding the Ginevro iron ore deposit, 30 m NN, W flank of the mining area.

The skarn bodies are irregular replacement bodies with characteristic mineral assemblages:

Sulfides: Pyrite, chalcopyrite, rarely galena Oxides: Magnetite (martite, Ti-free), hematite Silicates: Ca-Mg-Fe-silicates (garnet, pyroxene, amphibole, epidote, ilvaite)

4.3.1 The Ginevro and Sassi Neri skarns

Isolated skarn bodies without sedimentary structures surrounded by the intensive and ductily deformed Calamita Schists are observed at the Ginevro (Fig. 4.3) and the Sassi Neri deposits (Fig. 1.2). The skarn areas of Ginevro and Sassi Neri differ from all other Elbanean skarns. The amphibole dominated skarns are characterized by veinlets (with bleached quartz-bearing rims and epidote minerals in the center), penetrating the surrounding Calamita Schists. Along fractures and other fluid migration paths the mafic components (mainly mica) of the Calamita Schists have been removed.

No primary carbonate can be observed in both deposits. Based on the occurring mineral association and observations from DIMANCHE (1974b), a metasomatic overprint of primary dolomite lenses can be concluded for the Ginevro and the Sassi Neri deposit.

The skarn and ore minerals appear mainly in coarse-grained, often almost monomineralic concentrations. Grossular and ilvaite are subordinate in these deposits. Not the expected paragenesis with magnetite, garnet and pyroxene (DIMANCHE & RUIZ, 1969), but an uncom-

mon skarn association has been found:

 $magnetite I + grossular + quartz \rightarrow pargasite/tremolite + magnetite II + ilvaite$

Small pargasite and euhedral magnetite crystals occur as inclusions in garnet. DIMANCHE (1969) described rims of andradite around grossular cores. In this study grossular was found exclusively. The grossular only occurs in amphibole lenses and not in the Calamita Schists outside the deposit. The analyzed pyroxene is zoned with salite cores and iron-rich rims of ferro-salitic composition. Two possible reactions describe the replacement of pyroxene (Chapter 3.1):

 $pyroxene \rightarrow ilvaite + calcite$ $pyroxene + magnetite \rightarrow ilvaite$

Subordinate xenomorphic ilvaite crystals are observed, and epidote, adularia, quartz and rarely calcite are concentrated in vugs and veins. Minor and dispersed amounts of pyrite occur.

4.3.2 The Capo Calamita skarns

The best diversification of skarn (and iron ore) zonation can be observed in the Capo Calamita deposit (Fig. 1.2). A typical pyrometasomatic sequence depending on the supposed distance to the pluton was formed. Three skarn bodies can be distinguished: Punta della Calamita, Vallone Alto (south of Palazzo) and Nuova Zona (Fig. 4.4, 4.5). Close to the plutonic contact an epidote skarn was formed in Vallone Basso (Fig. 4.4), followed by a garnet-pyroxene-skarn with magnetite and, towards the north, by pure marble with single magnetite crystals and euhedral pyrite, probably with increasing distance to the pluton. In the Nuova Zona an almost monomineralic garnet skarn is exposed.

Quartz can be observed in the parageneses, perhaps as a result of complete consumption of SiO_2 in the replacement reaction. Remnants of pyroxene occur as inclusion in garnet and amphibole in the skarnified areas of the Capo Calamita deposit.

The zoned skarn bodies refer to a high temperature gradient between cold host rock and hot fluid. Thus, the zonation shows a "frozen system" of skarn formation, usually formed in an non-equilibrated system (ZHARIKOV, 1970a,b), as is customary for contact metamorphism.

4.3.2.1 Skarn Punta della Calamita

On the south coast of the Calamita peninsula, at Punta della Calamita (Fig. 4.5), a skarn body of several tenths of meters occurs, containing metasomatic minerals of several centimeters, such as ilvaite, ferro-actinolite, magnetite, pyrite and andradite. An unskarnified marble wedge underlies the skarn-ore body in sharp contact and without evidence of tectonic emplacement. Locally, the recrystallized minerals mimic the natural carbonate bedding. The sizable zonation of the skarn body shows mainly ferro-actinolite in the SE part, massive ilvaite towards the NW, up to a magnetite-dominated NW zone:

• Radial fibrous ferro-actinolite, pyrite up to 1.5 cm in diameter and subordinate ilvaite occur in the SE part of Punta della Calamita.

Figure 4.4: The Capo Calamita deposit: (1) Civetta, (2) Albaroccia, (3) Nuova zona, (4) Macei Alto, (5) Polveraio, (6) Coti Nere, (7) Le Piane, (8) Punta Rossa, (9) Macei Basso, (10) Vallone Alto, (11) Vallone Basso (after CALANCHI et al., 1976).

Tübinger Geowiss. Arb. Reihe A, 65 (2002)

Figure 4.6: Ilvaite crystals from the Capo Calamita deposit, showing a distinct pleochroism from reddish-brown to yellowish-brown in reflected light. White: Magnetite replacing ilvaite. (Width = 550 μ m, oil immersion).

- Ilvaite up to 20 cm in length dominates the subsequent zone towards NW. The sorosilicate is nearly opaque in transmitted light and shows a distinct pleochroism from reddishbrown to yellowish-brown in reflected light (Fig. 4.6).
- Mainly magnetite follows towards the NW in an abandoned mine area.

Needles of ferro-actinolite and uralite overgrow the mineral association, and later veinlets of epidote, quartz and calcite penetrate the skarn bodies.

4.3.2.2 Skarn south of Palazzo

Epidote builds up the SE flank below the locality Palazzo and west of Laveria (Fig. 4.4). Magnetite veins of several centimeters crosscut the skarn body. In Vallone Alto, the epidote skarn changes to a magnetite dominated ore body with sharp contact to the overlying unskarnified marble (Fig. 4.5). Towards the NW, a garnet-rich, almost monomineralic zone of andradite, with calcite and magnetite in the interstices follows (Fig. 3.20). An older magnetite generation (mag I) embedded in andradite, occurs (Fig. 3.31). The garnet is partly replaced by ferro-actinolite (Fig. 3.23). In transmitted light, the andradite occurs in veins locally anisotropic or multiply zoned (below detection limit of the electron microprobe, see Chapter 3). The unskarnified marble in Vallone Alto does not show any skarn minerals. Pyrite and iron oxides are absent, too. There is no primary bedding visible in the pure, irregulary jointed marble.

4.3.2.3 Skarn of Nuova Zona

SE of the mining area Nuova Zona an almost monomineralic garnet skarn body is exposed (Fig. 4.5). Towards the north, ferro-salite, ferro-actinolite and less abundant magnetite and

ilvaite occur besides andradite. Two generations of andradite can be distinguished: multiply zoned and locally anisotropic minerals besides unzoned, coarse-grained masses of andradite. Pyroxene (ferrosalite) is subordinate in Nuova Zona. In general, an overlap of skarn and ore formation with two main skarn formation periods can be distinguished within the Capo Calamita deposit (Chapter 2, Fig. 2.9). Euhedral magnetite crystals (mag II) occur in zoned andradite of the first formation stage. The andradite is partly replaced by younger ferro-actinolite. Ilvaite replaces ferro-actinolite and magnetite (mag III) replaces ilvaite. Magnetite veins of several centimeters in diameter crosscut the epidote skarn south of Palazzo.

4.3.3 The Terra Nera skarn

A small skarn body (3 x 1.6 m^2) is surounded by an unskarnified cataclastic zone of the Zuccale Detachment Fault (ZDF), underlying the Terra Nera deposit (Fig. 1.2). The skarn contains epidote, hedenbergite, calcite and garnet of several millimeters in diameter (SEECK, 1998). The skarn body is crosscut by the ZDF and therefore older than the ZDF. The skarn slice is covered with an unknown green, lamellar, fine-crystalline and immeasurable mineral "felt", overgrowing the whole mineral association. In other parts of the Terra Nera deposit no skarn mineralizations were found.

4.3.4 Skarn Torre di Rio Marina

South of the Rio Marina deposit, at the port of Rio Marina, a ca. 30 x 100 m² sized skarn, with sharp contact to the unskarnified marble, is present. The heterogeneous skarn shows magnetite - garnet - salite - tremolite - layers (thickness up to several centimeters), precipitated in the bedding plane of the skarnified marble. Depending on the quantity of iron, tremolite, epidote or ilvaite layers were observed; ilvaite formed in the iron rich layers. Around 150 m south of the Torre di Rio Marina at the coast, several square meters of almost monomineralic ilvaite (sized several millimeters in diameter) is exposed. Subordinately, pyrrhotite and needles of tremolitic composition, as well as calcite and quartz in the interstices have been observed. The skarn body is mainly covered with an uncertain green, lamellar and fine-crystalline mineral "felt", probably tremolite, growing from quratz-rich zones into the calcite interstices. Fragments of unskarnified marble surrounded by calc-silicate rocks, without tectonic contact, confirm the pyrometasomatic and fluid related genesis. Minor pyrite (py II, Chapter 2) of several millimeters in diameter occurs within the skarn area.

In the Rio Marina deposit, ilvaite minerals as inclusions in pyrite of the youngest generation (py II, Chapter 2) were found.

4.3.5 Skarn Il Porticciolo

3 km south of Rio Marina (Fig. 1.2), a tectonically bound skarn area between porphyroid ("Ortano-gneiss") and calc-phyllitic schists, both belonging to Complex II (TREVISAN, 1950), characterizes the east coast. The alteration at II Porticciolo replaced the mineral stock of the host rocks almost completely. Radial "suns" of tremolite occur, besides minor magnetite, epidote in veinlets, as well as pyrrhotite and calcite in the interstices (Fig. 3.15). Within the gneiss (Complex II) rarely veins of quartz-actinolitic composition have been observed, which are probably connected with the skarn (because of the mineral assemblage).

4.4 The occurrence of ilvaite

The black orthorhombic or monocline sorosilicate ilvaite $CaFe_2^{2+}Fe^{3+}[OH|O|Si_2O_7]$ preferably occurs in a Ca-Fe-Si-C-O system of carbonate-related skarn deposits (COCCO & GARAVELLI, 1954; BURT, 1971b,c; PLIMER & ASHLEY, 1978; PESQUERA & VELASCO, 1986). The infrequent, mixed-valence iron silicate is typically formed during contact metamorphism as a late phase in skarn deposits or in igneous rocks as a late-stage alteration product. Subordinately, ilvaite is found in regionally metamorphosed serpentinite, e.g. in W-Liguria in the "Gruppo de Voltri", where metaophiolites (rodingites) occur (DIETRICH, 1972b). LUCCHETTI (1989) described ilvaite formation under high pressure conditions (p > 10 kbar, ca. 35 km depth). Ilvaite with a Mn-content of up to 6 % was observed in mud from the Red Sea, 2 km below sea level (WEISS et al., 1980).

In late metasomatism, ilvaite - often associated with quartz - replaces magnetite and is altered to goethite/limonite. KRÄUTNER & MEDESAN (1969) described ilvaite as pyrometasomatic replacement product under silicon supply.

The polyphase ilvaite-bearing host rocks of Elba are different in mineralogy. First low-grade regional-metamorphism affected the Calamita Schists (DÜNKEL, 2001) in the southern part of the studied area, whereas limestones, marbles and quartzitic schists occur in the northern parts. A younger, contact metamorphic and ilvaite-forming phase is associated with garnet, clinopyroxene, amphibole, pyrite and magnetite (Chapter 3).

Ilvaite is located in skarn areas along the east coast of Elba Island in four areas:

- Subordinately as xenomorphic remnants of several millimeters in diameter in the Ginevro deposit.
- In Capo Calamita skarn deposits, locally rock-forming.
- South of the Torre di Rio Marina, at a famous coast-exposure.
- Rarely, ilvaite occurs as inclusions in pyrite from the Rio Marina deposit, described in this study for the first time.

Elbanean skarns show the hydrous iron silicate associated with quartz and in paragenesis with ferro-actinolite, andradite and magnetite (BARTHOLOMÉ & DIMANCHE, 1967). Ilvaite occurs as idiomorphic, prismatic minerals up to 20 cm in length, as subhedral and radial-columnar crystals (Fig. 4.6).

The rareness of ilvaite in skarns is due to its dependency on the oxygen fugacity and its small stability field (BARTHOLOMÉ & DIMANCHE, 1967; BURT, 1971b; GUSTAFSON, 1974; LUCCHETTI, 1989). The stability of the ilvaite-quartz-magnetite assemblage is documented in the system CaO-FeO-O-SiO₂-H₂O (Fig. 4.8 - 4.13, BURT (1971b); BURTON & TAYLOR (1982); GUSTAFSON (1974)).

No exact estimation of formation conditions can be made, because many parameters, like chemical compositions of fluid phase and host rock, pressure, fugacities etc., are involved. The mole fraction X_{CO_2} usually increases from the pluton in direction to distal carbonate, assuming high X_{CO_2} content for the northern Elbanean deposits (BURT, 1971c; GUSTAFSON, 1974). The formation of ilvaite in CO_2 -bearing systems is restricted to low f_{O_2} and high iron content (YAQUIAN & JIBAO, 1993; CARROZZINI, 1994). Supposing low f_{O_2} values and a suspected X_{CO_2} near the intrusive body of 0.1, wollastonite should occur above 500°C (EINAUDI et al., 1981; HARRIS & EINAUDI, 1982). Nevertheless, the frequent retrograde alteration possibly erased former mineral generations.

SUMMARY

4.5 Summary

- The Elbanean skarns can be classified as shallow and altered exoskarns, containing Caand Fe-rich silicates. The contact pneumatolytic replacement deposits (EINAUDI et al., 1981) and skarn areas are mostly unzoned, which indicates relatively fast formation conditions. Predominantly sharp and discordant contacts to the unskarnified host rocks occur. Brittle deformation dominates folding in all deposits.
- The skarn areas of Ginevro and Sassi Neri differ from the other Elbanean skarns. The amphibole dominated lenses with minor pyroxene and garnet are characterized by veinlets of bleached quartz-bearing rims and epidote in the center, penetrating the surrounding Calamita Schists. Grossular and ilvaite are subordinate in these deposits.
- No primary carbonate can be observed in the Ginevro and Sassi Neri deposit. Based on the mineral associations and observations from DIMANCHE (1974b), a metasomatic overprint of primary dolomite lenses is assumed for the Ginevro and the Sassi Neri deposit.
- The skarns of Capo Calamita, Rio Marina and subordinate Terra Nera belong to a different skarn type, exposing a high and mainly similar mineral diversity. The Capo Calamita and the Rio Marina skarn show sharp contacts to the unskarnified marbles. Within several centimeters, the primary bedding of the host rock is visible, but within medium to long distances, skarn formation does not strictly follow lithological boundaries.
- Two major skarn formation phases are discriminated for the Capo Calamita deposit (for details see Chapter 2):
 - 1) Ferrosalite, andradite, magnetite II, ilvaite, hematite II, quartz
 - 2) Pyrrhotite, ferro-actinolite, ilvaite, magnetite III, epidote, calcite, quartz
- The zoned skarn bodies from Capo Calamita refer to a high temperature gradient between cold host rock and hot fluid. Thus the zonation shows a "frozen system" of skarn formation, usually formed in an non-equilibrated system (ZHARIKOV, 1970a,b), as is customary for contact metamorphism.
- The exoskarns are altered by circulating fluids. Supercritical gas discharge due to pressure relief caused both vaporization and distillation processes in the wall rock (EINAUDI et al., 1981). The shallow East Elba pluton with temperatures not exceeding 650°C (at the contact aureole of the intrusive body and in the surrounding wall rocks, DIMANCHE (1971)) enabled the formation of wollastonite only in the inner contact zone.
- Depending on the porosity and permeability of the infiltrated host rock, reaction rims emerge, which block the dispersion of the reaction front (EINAUDI et al., 1981). Therefore, the fluid transport is focused in directon of maximum permeability (DIPPLE & GERDES, 1998). Also fragments of unskarnified marble, as exposed in Capo Calamita and Rio Marina, surrounded by calc-silicate rocks and without tectonic contact, confirm the metasomatic and fluid related genesis.

- In Elbanean skarns during late metasomatism, ilvaite often associated with quartz replaces magnetite and is altered to goethite/limonite (EINAUDI et al., 1981; EINAUDI & BURT, 1982). KRÄUTNER & MEDESAN (1969) described ilvaite as pyrometasomatic replacement product under silicon supply.
- The huge size of ilvaite crystals, up to 20 cm in length, in the Capo Calamita deposit as well as the almost monomineralic ilvaite zone south of the Torre di Rio Marina, can be explained by a large volume of saturated fluid, assuming constant formation conditions with time and the absence of a high temperature gradient in this zone. In the Ginevro deposit the situation is different. Here, small and xenomorphic ilvaite crystals were mainly replaced by magnetite and vice versa, probably indicating a high temperature gradient.
- The Rio Marina deposit does not show skarn mineralization, except of minor "strayed" ilvaite crystals included in the youngest pyrite generation. Even the transported carbonate-bearing wedge in the Rio Marina deposit do not contain calc-silicates or iron ores. Only a minor amount of the youngest pyrite generation occurs in the carbonatic slice.
- The stability of the ilvaite-quartz-magnetite assemblage can not be estimated exactly, because many parameters, like chemical compositions of fluid phase and host rock, pressure, fugacities etc., are involved. The mole fraction X_{CO_2} usually increases from the pluton in direction to distal carbonate, assuming high X_{CO_2} content for the northern Elbanean deposits (BURT, 1971c; GUSTAFSON, 1974).
- The formation of ilvaite in Elba, in a low pressure CO₂-bearing system is restricted to low f_{O_2} and high iron concentration (YAQUIAN & JIBAO, 1993; CARROZZINI, 1994). Supposing low f_{O_2} values and a suspected X_{CO_2} near the intrusive body of 0.1, wollastonite should occur above 500°C (EINAUDI et al., 1981; HARRIS & EINAUDI, 1982). Nevertheless, the frequent retrograde alteration possibly erased former mineral generations.
- All skarn areas are locally covered with an unknown green, lamellar and fine-crystalline mineral "felt" of probably tremolitic composition (incapable of measurement), over-growing the mineral assemblages.

4.6 Phase equilibria of skarn deposits

Skarn formation includes a wide range of potentially ore-forming environments. Most geochemical studies of skarn deposits have focused on mineral phase equilibrium, fluid inclusions and isotopic investigations of fluid sources and pathways. Experimental phase equilibrium studies and an internally-consistent thermodynamic database to model potential skarnforming solutions (e.g. FLOWERS & HELGESON (1983); FERRY & BAUMGARTNER (1987); JOHNSON & NORTON (1984, 1985)) are essential for clarifying mineral reactions. Fractionation of elements between minerals can also be used to estimate conditions of skarn formation. A general review of phase equilibria applicable to skarn systems is presented by BOWMAN (1998). A more specialized treatment of the vector representation of skarn mineral stabilities is presented by BURT (1998). DIPPLE & GERDES (1998) integrated standard phase equilibria treatment of skarn mineralogy with fluid dynamics, in order to model the metasomatic evolution of skarn systems.

Figure 4.7: Projections of log f_{O_2} - temp stability range of pure andradite and pure hedenbergite at 2 kbars fluid pressure. The region between the two univariant curves indicates the f_{O_2} - temp range where both phases can coexist (after GUSTAFSON, 1974). Note the maximum range of estimated values of f_{O_2} between 10⁻¹⁸ bar (hedenbergite in) and 10⁻³³ bar (andradite out) relevant for the reaction andradite-hedenbergite in Elbanean skarns.

4.6.1 Phase equilibria in the system Ca-Fe-Si-O

The paragenetic relations, developed during metamorphism of siliceous dolomites, limestones and iron-rich calc-silicate skarns, have been investigated in detail by BURT (1971a,b,c) for the system Ca-Fe-Si-C-O-H. However, only little experimental work has been done on this system. ERNST (1966) showed a breakdown curve for hedenbergitic pyroxene to form andradite + magnetite + quartz with increasing f_{O_2} . GUSTAFSON (1974) determined the maximum stability limits of pure andradite and hedenbergite over a wide temp - P_{fluid} - f_{O_2} range (Fig. 4.7). With the knowledge of the stability of hedenbergite, GUSTAFSON (1974) restricted the stability field of ilvaite as documented in Fig. 4.9, 4.10 and 4.11.

Following REDHAMMER et al. (2000), clinopyroxene is a stable phase (with hematite-magnetite buffer) in the temperature range between 350° and 780°C. Depending on the oxygen fugacity (f_{O_2}) , the stability diagram for a selected clinopyroxene composition at 4 kbar is given in Fig. 4.8. For the Elbanean deposits with temperatures not exceeding 500°C (DIMANCHE & RUIZ, 1969; DIMANCHE, 1971; DÜNKEL, 2001), the oxygen fugacity for the mineral pair pyroxene (hedenbergite) - andradite is restricted to $f_{O_2} \leq 10^{-17}$ bar (REDHAMMER et al., 2000). Note, that the following equation shows the end-member composition of the occurring mineral reaction and represents an approximation:

$$\begin{array}{rcrcrcrc} 9CaFe(Si_2O_6) + 2 & O_2 & \rightarrow & 3Ca_3Fe_2Si_3O_{12} & + & Fe_3O_4 & + & 9SiO_2 \\ pyroxene & & andradite & magnetite & quartz \end{array}$$

Gustafson (1974) confirms that the range of oxygen fugacity of f_{O_2} is between 10⁻¹⁸ and 10⁻³³ bar for Elba.

For mineral phases in Ca-Fe-Si skarns BURT (1971a,c) described an isobaric, isothermal μ_{O_2} -

Figure 4.8: Temperature versus log f_{O_2} stability diagram for a hedenbergitic composition, comparable to the Elbanean conditions, at 4 kbar. The solid line corresponds to the stability boundary (after REDHAMMER et al. (2000)). Note that the temperatures of the Elbanean deposits did not exceed 600 °C (Chapter 5); HM: Hematite-magnetite buffer; QMF: Quartz-magnetite-fayalite buffer.

 μ_{CO_2} diagram (Fig. 4.9), where μ defines the chemical potential. During skarn formation the partial pressure of CO₂ is probably much less than the total pressure (the dominant species is H₂O) and both, μ_{O_2} and μ_{CO_2} are externally controlled. The diagram (Fig. 4.9) shows the topological relationships of mineral stability fields over broad ranges of pressure and temperature (in the range 300° to 600°C and 2 to 3 kbars). Yet reliable thermochemical data are still lacking, therefore, the phase diagrams are drawn for unspecified temperatures, pressures and chemical potentials.

P, T, μ_{O_2} , and μ_{CO_2} are not the only variables affecting the stability of Ca-Fe-Si skarn minerals. Gradients in the μ_{Ca} , μ_{Fe} and μ_{Si} must have existed across the skarns, as indicated by the monomineralic zones typical of the Capo Calamita deposit. Elements, such as helium, sulfur, fluorine, boron and iron, played important roles, especially during late stage, low-temperature processes. In some Japanese skarn deposits (BURT, 1971a), early skarn assemblages clearly show a time-dependent trend. The direction of these Japanese changes is indicated schematically by arrows in Fig. 4.9. The grey field (Fig. 4.9) shows the approximate location at which the Elbanean skarn assemblage: andradite (And) + hedenbergite (Hed) + ilvaite (Ilv) was formed and ilvaite appears in the third dimension; note also the different scale: μ_{CO_2} increases double compared to μ_{O_2} .

4.6.2 Stability of ilvaite

Due to the restricted oxygen fugacity and the limitation of the chemical potential by the assemblage and radite-hedenbergite-ilvaite, GUSTAFSON (1974) limited the stability conditions particularly of ilvaite even more. On the expanded f_{O_2} - temp diagram (Fig. 4.10), the high-temperature breakdown of ilvaite is shown:

• At high oxygen fugacity, near the magnetite-hematite (MH) buffer and higher:

$$9CaFe_3(Si_2O_7)O(OH) + 2.75O_2 \rightleftharpoons 3Ca_3Fe_2(SiO_4)_3 + 9SiO_2 + 7Fe_3O_4 + 4.5H_2O_{ilvaite}$$

Figure 4.9: Schematic isobaric, isothermal $\mu_{O_2} - 2\mu_{CO_2}$ stability diagram of the system Ca-Fe-Si-C-O for the facies of different skarns. The grey field shows the approximate location in $\mu_{O_2}-2\mu_{CO_2}$ at which the Elbanean skarn assemblage: andradite (And) + hedenbergite (Hed) + ilvaite (Ilv) was formed. Arrows show approximate changes of conditions over time for several Japanese skarn deposits and one skarn assemblage is exemplarily graphical documented (from BURT, 1971c); Qtz = quartz, Po = pyrrhotite, Fay = fayalite, Wol = wollastonite, Hem = hematite, Mag = magnetite, Cal = calcite.

• At moderate and low f_{O_2} in the vicinity of the nickel-nickel oxide (NNO) buffer and under more reducing conditions:

The stability field of the reaction (ilvaite \Rightarrow hedenbergite + magnetite) of pure end members described above is given in Fig. 4.11. ERNST (1966) synthesized ilvaite at relatively high oxygen fugacities below approximately 450°C. But the hedenbergite in the study of ERNST (1966) was not pure, containing variable amounts of ferrosilite (FeSiO₃). In this case, ilvaite no longer plots in the area magnetite-hedenbergite. Thus, stoichiometric ilvaite cannot form from the reaction of magnetite + hedenbergite, if the bulk composition lies below this region.

Figure 4.10: Stable isobaric invariant points involving the phases and radite (Ad), hedenbergite (Hd), quartz (Qt), magnetite (Mt), wollastonite (Wo), xonotlite (Xo; $Ca_6(Si_6O_{17})(OH)_2)$, kirschsteinite (Kr; CaFeSiO₄), ilvaite (Iv) and vapor (fluid; V). The grey dot locates the isobaric invariant point of the relevant coexisting phases Ad + Hd + Qt + Mt + Iv + V for Elbanean skarns (from GUSTAFSON (1974)).

4.6.3 Fluid fugacities in the Fe-Si-O-H-S system

On Elba island an alternating crystallization of hematite and magnetite generations (of different oxidation stages), occurs without conspicuous trace element enrichments, as discussed in Chapter 2 and 3. A mainly continuous pyrometasomatic to hydrothermal cooling process at temperatures below 500°C and ca. 1 kbar can be assumed (DIMANCHE & RUIZ, 1969; DIMANCHE, 1971; DÜNKEL, 2001), apart from variable element concentrations in the fluid, depending on different fluid sources or pathways through different host rocks.

Based on experimental data of univariant reactions depending on sulfur activity (BARNES (1979), Fig. 4.12) and pressure, subjected to the Fe-Si-O-H-S system (SHI (1992), Fig. 4.14), variations in mainly oxygen and sulfide fugacities (BURT, 1971b; SHI, 1992) result in the replacement of older hematite and magnetite generations.

Figure 4.11: $\log f_{O_2}$ - temperature diagram for the reaction ilvaite + $O_2 \rightleftharpoons$ hedenbergite + magnetite + H_2O at $P_{\text{fluid}} = 2$ kbar, from GUSTAFSON (1974). NNO: nickel-nickel oxide buffer; FMQ: fayalite-magnetite-quartz buffer.

With decreasing temperature the stable mineral assemblages change from starting pyritemagnetite formation to stable pyrite-hematite formation. The fugacity corresponds to the activity, describing the effective sulfur concentration under non-ideal conditions (BARNES, 1979). For example at temperatures below 500°C: Pyrite forms at relatively high a_{S_2} . Hematite occurs at decreasing a_{S_2} , while magnetite precipitates at lower a_{S_2} , increasing f_{O_2} or at higher temperature.

The knowledge of heterogeneous equilibria in the Fe-Si-O-H-S system is also a prerequisite for the understanding of redox conditions, fluid fugacities and phase relations in the Elbanean skarn formation system. The quartz saturated Fe-Si-O-H-S system (SHI, 1992) allows to estimate fluid fugacities and phase equilibria in carbonate-silicate-oxide-sulfide-fluid systems in the relevant crustal temperature and pressure range.

For this study, the theoretical phase diagrams of the hematite-magnetite-pyrite buffer, based on experimental data from SHI (1992), delimit the composition of the involved fluid phase, applicable for a simplified one-phase cooling process near the plutonic contact.

The hematite-magnetite-pyrite (HMPy) f_{O_2} - f_{S_2} buffer:

The HMPy equilibrium is controlled by the univariant O-buffering reaction hematite-magnetite (HM) and two divariant reactions MPy and HPy. The pressure dependence is much smaller than the temperature dependence for the HMPy buffer, and the f_{S_2} values increase with increasing temperature and decreasing pressure (SHI, 1992). Fig. 4.13 shows the temperature-pressure relations for f_{H_2S} , f_{SO_2} , f_{H_2} and f_{H_2O} in the HMPy assemblage.

One can conclude from this diagram that H₂S is the dominant S-bearing species in the fluid

Figure 4.12: Sulfur activity of different iron oxides versus temperature. The fugacity corresponds to the activity, describing the effective sulfur concentration under non-ideal conditions (BARNES, 1979). For example at temperatures below 500°C: formation of pyrite at relatively high a_{S_2} . Hematite occurs at decreasing a_{S_2} , while magnetite precipitates at lower a_{S_2} , increasing f_{O_2} or at higher temperature.

Figure 4.13: log f_i - temperature - pressure relations of the hematite-magnetite-pyrite-H₂O buffering assemblages at 1, 5 and 10 kbar. H₂S is the dominant S-bearing species in the fluid phase at low temperatures and SO₂ is the most abundant S-bearing species at high temperatures; $f_i = f_{SO_2}$ or f_{H_2} or f_{H_2S} or f_{H_2O} (from SHI, 1992).

Figure 4.14: log f_{O_2} - log f_{S_2} phase diagrams for the quartz-saturated system Fe-Si-O-H-S at 2 kbar and a) 400°C and b) 600°C (from SHI, 1992). Note the shift of stability fields with decreasing temperatures towards lower f_{O_2} and f_{S_2} values. For the Terra Nera deposit, a simplified (grey) crystallization area, without regard to cooling, is shown. The supposed pressure of 2 kbar is slightly too high, which results for the shallow Elba deposits in an unimportant shift towards higher fugacities; po = pyrrhotite; py = pyrite; mag = magnetite; fay = fayalite; hem = hematite; wus = wüstite; Fe = iron.

Figure 4.15: log f_i - temperature phase diagrams for invariant reactions at 2 kbar for the Fe-Si-O-H-S system. a) O₂, b) S₂, c) SO₂, d) H₂, e) H₂O, f) H₂S. The dashed lines (sulfide out) illustrate the upper limits of stabilities for pyrite- and pyrrhotite-bearing assemblages. The complete legend is listed in Fig. 4.14, from SHI (1992).

(11) (11) (12) (13) (14)	Fe-act + 3cc + 2qtz	$\rightarrow 5\text{hed} + 3\text{CO}_2 + \text{H}_2\text{O}$ $\rightarrow 4\text{Fe-act} + 22\text{cc} + 5\text{O}_2$ $\rightarrow 18\text{Fe-act} + 17\text{O}_2$ $\rightarrow 6\text{Fe-act} + 5\text{O}_2 + 12\text{CO}_2$

phase at low temperatures (relevant for Elbanean deposits), and SO₂ is the most abundant S-bearing species at high temperatures (above 500°C). f_{H_2O} and f_{H_2} decrease with decreasing pressure (Fig. 4.13).

At a given temperature, pyrite may be oxidized to hematite lowering f_{S_2} at fixed f_{O_2} (Fig. 4.14). Or hematite may be replaced by pyrite lowering f_{O_2} at fixed f_{S_2} . Magnetite may be replaced by hematite increasing f_{O_2} and by pyrite increasing f_{S_2} (Fig. 4.14).

However, the log f_{S_2} curve of the HMPy buffer will never cross the same curve of another buffer at any temperature or pressure (SHI (1992), Fig. 4.15). Thus, pyrrhotite is never in equilibrium with coexisting hematite and magnetite. The study of SHI (1992) also specifies the upper limits of f_{O_2} and f_{S_2} for HPy and MPy nonbuffering assemblages at different temperatures and a pressure of 2 kbars (Fig. 4.14). The stability fields shift with decreasing temperatures towards lower f_{O_2} and f_{S_2} values.

Fig. 4.15 shows the f_{O_2} , f_{S_2} , f_{SO_2} , f_{H_2} , f_{H_2O} and f_{H_2S} for different invariant reactions at a pressure of 2 kbars and various temperatures. The diagram also illustrates the upper limits of stabilities for the pyrite- and pyrrhotite-bearing assemblages. Note the increasing stability field for the assemblage hematite-pyrite with decreasing temperature.

4.6.4 Constraints on f_{O_2} and a_{CO_2}

The replacement of the Ca- and Fe-bearing mineral assemblages are probably based on local variations in f_{O_2} , a_{H_2O} or a_{CO_2} . The activity can be thought of as effective mole fraction of a component in a nonideal solution, just as the fugacity is the effective pressure of a nonideal gas. In order to constrict the prevailing conditions, an f_{O_2} - a_{CO_2} diagram was calculated for the deposits of Ginevro and Capo Calamita in the Ca-Fe-Si-O-H-C system, depending on magnetite, hedenbergite, andradite, ferro-actinolite, calcite, quartz, CO₂ and

Figure 4.16: The f_{O_2} - a_{CO_2} diagram (Fig. 4.17) showing the involved reactions (Table 4.1) in order to clarify the various Ca-bearing skarn assemblages ranging between (a) 600°C, (b) 500°C, (c) 400°C and (d) 300°C. The diagram is based on a pressure of 1 kbar and calculated activities of $a_{and} = 0.8$, $a_{hed} = 0.8$, $a_{cc} = 0.9$ and $a_{Fe-act} = 0.06$. The position of invariant points shift with decreasing temperature towards lower f_{O_2} and lower a_{CO_2} values. Grey dots: Invariant points of hedenbergite (hed), ferro-actinolite (Fe-act), magnetite (mag), quartz (qtz). Note the increasing stability field in-between the invariant points during cooling of the system.

Figure 4.17: The zoomed $f_{O_2} - a_{CO_2}$ diagram (out of Fig. 4.16) shows the reactions (1)-(5), Table 4.1 together with the synthetic fayalite-magnetite-quartz (FMQ) buffer curve in order to clarify the various Ca-bearing skarn assemblages. In the range of 300-600°C the position of the invariant point (ferro-actinolite) shifts with decreasing temperature towards lower f_{O_2} and a_{CO_2} values (grey dots) from log $f_{O_2} = -22.4$ bar at 600°C to -38.2 bar at 300°C, while log a_{CO_2} changes from -0.1 at 600°C to -2.2 at 300°C. Dotted lines: Exemplarily shown reaction lines for 400°C and $a_{hed} = 0.05$.

Table 4.2: Mineral reactions involving magnetite (mag), nedenbergite (ned), andradite (and), ferro-
actinolite (Fe-act), calcite (cc) and quartz (qtz). The diagram is based on a pressure of 1 kbar,
calculated activities of $a_{and} = 0.8$, $a_{cc} = 0.9$, $a_{Fe-act} = 0.06$ and the min. value of $a_{hed} = 0.05$, repre-
sentative for the east flank of the Capo Calamita deposit.

CONCLUSIONS

H₂O (GEO-CALC, BERMAN et al. (1987); LIEBERMAN & PETRAKAKIS (1990)). Due to the thermodynamic database of BERMAN (1988) and GHIORSO & EVANS (2002) isothermic log f_{O_2} - log a_{CO_2} diagrams from 300°C up to 600°C were calculated in order to clarify the various Ca-bearing skarn assemblages.

Magnetite was regarded as a pure end member in accordance with microprobe analyses (Chapter 3). The solution model of HOLLAND (1990) is used for the calculation of end member activities for hedenbergite, that of COSCA et al. (1986) for andradite and a "mixing on site" model for calcite and ferro-actinolite.

The resulting activities $(a_{and} = 0.8, a_{cc} = 0.9, a_{Fe-act} = 0.06 \text{ and } a_{hed} = 0.8)$ were plotted in a f_{O_2} - a_{CO_2} diagram (Fig. 4.16) for 300°, 400°, 500° and 600°C, showing the involved reactions (Table 4.1). In the range of 300-600°C the topologic relations between the reactions (1)-(14) are not similar and the position of the invariant points shift with decreasing temperature (Fig. 4.16, 4.17). The zoomed invariant point for ferro-actinolite (HELLNER & SCHURMANN (1966), Fig. 4.17) for example shifts from log $f_{O_2} = -22.4$ bar at 600°C to -38.2 bar at 300°C, while log a_{CO_2} changes from -0.1 to -2.2, as well as the synthetic fayalite-magnetite-quartz buffer curve decreases with decreasing temperature.

Note, that the maximum range of a_{hed} between 0.8 (Fig. 4.16) and 0.05 (occurring at the east flank of the Capo Calamita deposit) is examplarily itemized for $a_{hed} = 0.05$ in Table 4.2 showing less involved reactions; whereas the other activities are stable. The invariant point of ferro-actinolite is situated for $a_{hed} = 0.05$ at higher log f_{O_2} and log a_{CO_2} related to $a_{hed} = 0.8$; for example at 500°C: $\Delta \log a_{CO_2} = 0.3$ and $\Delta \log f_{O_2} = 5.34$.

The f_{O_2} - a_{CO_2} diagram restricts the different Ca-mineral assemblages:

Assuming a temperature of 400°C, the formation of andradite (reaction (3), grey area in Fig. 4.17) refers to a fluid phase with log $a_{CO_2} < -1$ ($a_{CO_2} < 0.1$). For 600°C andradite points to a higher CO₂ activity with $a_{CO_2} < -0.1$ ($a_{CO_2} < 0.8$).

The carbonate-bearing samples from the Capo Calamita deposit indicate higher f_{O_2} and higher a_{CO_2} values (white area) and gave minimum values for $a_{hed} = 0.05$. Salite-bearing samples were less oxidized (dotted area) and show lower a_{CO_2} values.

The temperature constraints are in good agreement with magmatic to hydrothermal trend proved for the Elbanean skarn formation. The formation of contact-metamorphic Ca-minerals between 600°C and 300°C refers to the above described estimations of f_{O_2} and a_{CO_2} .

4.7 Conclusions

- The typical contact metamorphic mineral ilvaite acts as a significant index mineral. Marginally dissolved ilvaite crystals included in pyrite from the Rio Marina deposit were formed by relatively high f_{S_2} . After GUSTAFSON (1974) the minimum level for formation of the surrounding pyrite mineral gave f_{S_2} around 10⁻⁴ bar (at 2 kbar and below 527°C), after GUSTAFSON (1974).
- The high temperature breakdown of ilvaite is given at high oxygen fugacity, near the magnetite-hematite buffer (MH) and above:

$$ilvaite \rightleftharpoons and radite + quartz + magnetite$$

At moderate and low f_{O_2} in the vicinity of the nickel-nickel oxide buffer (NNO) and

CONCLUSIONS

under more reducing conditions (for the fayalite-magnetite-quartz buffer):

$ilvaite \rightleftharpoons hedenbergite + magnetite$

These appraisals are in good agreement with the formation conditions of hedenbergite (Fig. 4.7). Relevant for the reaction and radite-hedenbergite in Elba are f_{O_2} between 10^{-33} bar and 10^{-18} bar, estimated after the maximum temperature appraisals of DI-MANCHE & RUIZ (1969); DIMANCHE (1971) and DÜNKEL (2001).

- Based on experimental data of univariant reactions depending on sulfur activity (BARNES (1979), Fig. 4.12) and pressure, subjected to the Fe-Si-O-H-S system (SHI (1992), Fig. 4.14), variations in mainly oxygen and sulfide fugacities (SHI, 1992; BURT, 1971b) result in the replacement of older hematite and magnetite generations.
 In the shallow Elbanean deposits (supposed pressure of 1 kbar) with decreasing temperature the stable mineral assemblages change from starting pyrite-magnetite formation to stable pyrite-hematite formation. Constraints are made according to Fig. 2.14 and the results are in good agreement with the observed geological and mineralogical processes discussed in Chapter 1-3.
- The supposed fluid phase composition of the hematite-magnetite-pyrite assemblage can also be estimated (Fig. 4.15, SHI (1992)) and presents a first approximation, based on experimental data applied to Elbanean deposits.
- It is possible to reconstruct the path along the reaction equilibrium of the involved minerals, as shown for the Terra Nera deposit in Fig. 4.14. In the Capo Calamita deposit a slightly lower oxygen-fugacity (f_{O_2}) resulted in the formation of pyrrhotite. The results are in agreement with the geological and mineralogical investigations described above, although the illustration (Fig. 4.14; SHI (1992)) does not consider the cooling of the system. Re-mobilisation combined with variation of the physico-chemical conditions causes the alternating crystallization of minerals.
- Activities representative for the deposits of Ginevro and Capo Calamita are $a_{and} = 0.8$, $a_{cc} = 0.9$, $a_{Fe-act} = 0.06$ and a_{hed} between 0.8 and 0.05, resulting in the mineral reactions shown in Table 4.1 and Table 4.2.
- Due to the thermodynamic database of BERMAN (1988) and GHIORSO & EVANS (2002) isothermic log f_{O_2} log a_{CO_2} diagrams were calculated for the Ginevro and the Capo Calamita deposit: Assuming a temperature of 400°C, the formation of andradite (Fig. 4.17) refers to a fluid phase with log $a_{CO_2} < -1$ ($a_{CO_2} < 0.1$). For 600°C andradite points to a higher CO₂ activity with $a_{CO_2} < -0.1$ ($a_{CO_2} < 0.8$).
- The carbonate-bearing samples from the Capo Calamita deposit indicate higher f_{O_2} and higher a_{CO_2} values and gave additionally minimum values for $a_{hed} = 0.05$. Salite-bearing samples were less oxidized (dotted area) and show lower a_{CO_2} values.
- The constraints on f_{O_2} and a_{CO_2} are in perfect agreement with the projections of log f_{O_2} temperature after GUSTAFSON (1974) and the estimated fluid fugacities in the Fe-Si-O-H-S system (SHI, 1992).

$C\!HAPT\!ER\ 4$

CONCLUSIONS

- The temperature constraints are in good agreement with magmatic to hydrothermal trend proved for the Elbanean skarn formation. The formation of contact-metamorphic Ca-minerals between 600°C and 300°C refers to the above described estimations of f_{O_2} and a_{CO_2} .
- Certainly, the genesis of the east Elba ore deposits cannot be finalized by this first approximation, based on experimental data. More detailed geochemical data (see Chapter 5 and 6) are required for a better understanding of the compositional variations of fluids and the emplacement of Elba iron ores.
Chapter 5

Isotopic studies

Isotopic investigations, particularly the stable isotopes of C, O and S are critically important in documenting the multiple fluids present in most skarn systems (RYE & OHMOTO, 1974; SHELTON, 1983; OHMOTO & GOLDHABER, 1997; BOWMAN, 1998). The pioneering study of TAYLOR (1971) demonstrated the importance of both magmatic and meteoric waters in the evolution of skarns. Fractionation or separation of naturally occurring stable isotopes occurs as a result of their different masses. Such a fractionation is common in all physicochemical processes such as vaporization, condensation, melting, crystallization or diffusion and by chemical reactions. Reaction rates and accompanying isotope exchange is a function of the species involved and their composition (ROLLINSON, 1993).

5.1 Sulfur isotopic study

Sulfur isotopic studies on a variety of sulfide minerals (including pyrite, pyrrhotite and chalcopyrite) from Elbanean deposits (Capo Calamita, Rio Marina, Il Porticciolo) have been examined in order to clarify the source of sulfur in ore forming fluids (Fig. 5.1).

First comparative studies on Elbanean and Tuscan pyrites were made by DESCHAMPS et al. (1983a) and DESCHAMPS et al. (1983b). First detailed sulfur isotopic studies were made in the context of a unpublished diploma thesis by ERZ (2000) within our "Elba-Project" supported by the Deutsche Forschungsgemeinschaft. The data of ERZ (2000) align with the outcome of this study and are included here.

5.1.1 Method

The S-isotope compositions were measured in an automated fashion, using a Carlo Erba (CE 2500) elemental analyzer linked to a Finnigan MAT Delta Plus XL mass spectrometer. The on-line continuous flow sulfur isotope measurements were performed according to the method of GIESEMANN et al. (1994). The samples were reacted at 1050°C in a He-carrier gas spiked with oxygen. The SO₂ produced was separated from other combustion gases by gas chromatography. Any SO₃ produced was reduced to SO₂ by passing the gas over metallic Cu held at 650°C.

Final results were calibrated against international standards (IAEA standards S 1 to S 3 and NBS 123 (ZnS)) with accepted values of -0.3, -32.1 and 17.1 %, respectively. The resulting δ^{34} S values are expressing the differences between the S-isotopic ratio of a sample relative

Figure 5.1: Variation of sulfur isotopic composition (δ^{34} S values in ‰) in rocks, waters and volcanic gases from HOEFS (1997), compared to those of Elbanean pyrites, pyrrhotites and chalcopyrites made by Erz (2000) and in this study.

to Cañon Diablo Troilite (CDT) in parts per thousand. The external reproducibility of the standards is better than 0.1 %.

$$\delta^{34}S = \left(\frac{({}^{34}S/{}^{32}S)_{sample}}{({}^{34}S/{}^{32}S)_{CDT}} - 1\right) \ge 1000$$

5.1.2 Possible sulfur sources

Seawater sulfate: Sulfur ions are always present in seawater, mainly as sulfate ions (Fig. 5.1). The δ^{34} S curve from CLAYPOOL et al. (1980) indicates values of 12 to 17 % for Triassic seawater, Miocene seawater sulfate is mainly in the range of 21 to 22 %. The inorganic fractionation between sulfate and sulfide is predominantely a function of temperature, f_{O_2} and pH (FAURE, 1986). Higher temperatures of precipitation result in smaller δ^{34} S fractionation between sulfate and sulfide ions.

For example, at 500°C H₂S should have δ^{34} S values about 14 ‰ lower and at 400°C about 17 ‰ lower than the original seawater sulfate. Hence, δ^{34} S values of 7 to 8 ‰ (or 3 to 4 ‰, respectively) are expected for precipitation of sulfides from Miocene seawater. δ^{34} S values close to the seawater isotopic composition should be the case for high-temperature formation of ore. High fractionation (resulting in light sulfides) refers to low-temperature deposits (OHMOTO & LASAGA, 1982).

Sulfur from surrounding rocks: Ore forming sulfur could be derived from the evaporitic rocks of the Upper Triassic cavernous limestones ("calcare cavernoso", see Chapter 1), which are in stratigraphic contact to the Verrucano Formation containing the northernmost deposits of Elba (Rio Marina and Rio Albano). These rocks of evaporitic origin contained gypsum, which may have provided sulfate ions to solution. Isotope exchange between sulfide already present in the fluid and dissolved sulfate from the "calcare cavernoso" formation changed the isotopic composition of total sulfur in solution relevant for pyrite precipitation.

Table 5.1: Sulfur isotopic composition (δ^{34} S, relative to Cañon Diablo Troilite (CDT), ± 0.3 error)
of pyrite, pyrrhotite and chalcopyrite from different Elbanean deposits; number of measurements $=$
10. Note the decrease in δ^{34} S values from N (Rio Marina) to S (Capo Calamita) and the low values
of the earlier ("older", see Chaper 2) species of chalcopyrite.

	$\delta^{34}\mathbf{S}\ [\%]$	$\delta^{34}\mathbf{S_{mean}} \ [\%]$

Chalcopyrite C. Calamita	5.59	
Chalcopyrite C. Calamita	5.65	5.62

Basaltic magmatism, as is for example represented by the ophiolite sequence of complex IV (TREVISAN (1950), see Chapter 1), may have initiated hydrothermal convection where sulfur from basaltic rocks might have been leached (SHANKS et al., 1981). But the known occurrences of Elbanean basaltic rocks are tectonically overlying the ore deposits, making the basalt-derived sulfur source unlikely. Nevertheless, basaltic rocks could be part of buried basement nappe stacks (FINETTI et al., 2001). Moreover, no significant concentration of organic material is known, which could have produced a relevant amount of H_2S .

Magmatic sulfur: The δ^{34} S values of magmatic sulfides ranges in general around zero $\%_0$ and show littler variation (Fig. 5.1). Ore deposits that are the result of a meteoric, metamorphism or sedimentation activity typically show a wider range of δ^{34} S values and tent to be higher (RYE & OHMOTO, 1974; GRAHAM & VALLEY, 1992; OHMOTO & GOLDHABER, 1997).

5.1.3 Results and discussion

Sulfur isotopic studies on a variety of sulfide minerals (pyrite, pyrrhotite and chalcopyrite) from Elbanean deposits, summarized in Fig. 5.1 and Table 5.1, indicate a very narrow range of δ^{34} S values. An overview of the ranges in δ^{34} S of pyrite (py II, see Chapter 2) and pyrrhotite in the deposits is given by ERZ (2000) in Fig. 5.2.

• The δ^{34} S values of all sulfides from east Elbanean deposits are rather homogeneous, ranging from δ^{34} S = 1.7 to 12.1 % (relative to CDT, ERZ (2000)). Low δ^{34} S values lie within the range considered typical for magmatic values (RYE & OHMOTO, 1974). The highest tempered deposit, Sassi Neri (Fig. 5.2), shows the lowest δ^{34} S values (δ^{34} S_{mean} = 1.7 %, ERZ (2000)). The close spatial relation of the Sassi Neri deposit

Figure 5.2: Sulfur isotopic composition of pyrite and pyrrhotite (Il Porticciolo) from different deposits from N to S; number of measurements = 123, after ERZ (2000).

Tübinger Geowiss. Arb. Reihe A, 65 (2002)

to the intrusive body, as well as $\delta^{34}S$ values close to zero, confirm a magmatic sulfur source (Erz, 2000).

- The increase of δ³⁴S values with increasing distance from the intrusion characterize the decreasing influence of magmatic sulfur towards the north and an increasing influence of sulfur derived from sedimentary wall rocks. The range of isotopic composition and distribution fits best with those known from ophiolitic rocks or magmatic sulfides. Mixing of magmatic sulfur with sulfur from the country rocks or an isotope exchange between intrusion-derived sulfur, with sulfate or sulfide ions from the surrounding rocks (including evaporites) along the fluid flow path (MEGAW, 1988) is possible for the more distal skarn bodies (e.g. Il Porticciolo).
- Although different lithologies (gneiss, limestones or sandstones, see Chapter 1) from the country rocks, there is only a small difference in isotopic composition of minerals in the ore or skarn bodies. Therefore the isotopic trend is attributed to a fluid dominated connvection system. The small variety of the δ^{34} S values argues against bio-mineralization but for an inorganic process as described detailed by KAJIWARA-YOSHIMICHI (1992) and LI-BIN (1993) for the Kutoko Mine, Japan.
- All δ^{34} S values within each deposit are normally distributed and rather homogeneous. No extreme high or low values occur within each deposit. This relatively small range in δ^{34} S values can be interpretes as one single magmatic source with high fluid:rock ratios. The samples from Rio Marina and Terra Nera show the most distinct variations in δ^{34} S values (Fig. 5.2). But no isotopic zoning between the center and the rim of the pyrites can be assumed. The outlier are small remnants or inpurities of ilvaite and mainly specularite, which is locally replaced by the analyzed, younger pyrite (Chapter 2).
- Contribution of bacteriogenetic sulfide is unlikely, because the δ^{34} S values are too high and the range in δ^{34} S values is too small (e.g. ELDRIDGE et al. (1988); PASSIER et al. (1999)). Moreover, an open sulfide-sulfate-system that would be required to generate the Elbanean sulfide formation commonly produces sulfides with δ^{34} S values up to -50 % (PASSIER et al., 1999).

Contribution of seawater sulfate and syn-Messinian ore formation as suggested by ARNOLD (1976), or epigenetic ore formation linked to seawater circulation in a convection system can be ruled out, because the conditions for inorganic sulfate reduction are not given in the geological context of Elba (ERZ, 2000).

Nevertheless, ARNOLD (1976) interpreted pyrite from the Rio Marina deposit (δ^{34} S values from -2.5 to 6.0 ± 0.5 ‰) as derived from seawater by bacterial sulfate reduction. But assuming upper Triassic seawater with δ^{34} S_{sulfate} values of 17 ‰ (RYE & OHMOTO, 1974; OHMOTO & GOLDHABER, 1997), bacterial reduction as a pyrite forming process would result in δ^{34} S below -23 ‰ (GOLDHABER & KAPLAN, 1974; CHAMBERS & TRUDINGER, 1979; PASSIER et al., 1999).

Besides, euhedral and framboidal pyrites from the sapropel in Pleistocene sediments from the eastern Mediterranean show δ^{34} S values below -40 % (PASSIER et al., 1999).

5.2 Oxygen isotopic study

Large scale interactions between cooling magma at shallow depth and large volumes of meteoric water or seawater is common and it is important to understand the origin of ore deposition and the related alteration of the country rock. Ore-bearing hydrothermal solutions (mobilized by igneous intrusives) and therefore present water, initially dissolved in the magma, is available to transport metals as complex ions or molecular in chlorine brines (TAYLOR, 1974). In order to interpret the analyzed data, it is necessary to know the equilibrium oxygen isotope fractionation factor between the minerals. The most common practice are oxygen isotope exchange measurements between mineral and water (CLAYTON et al., 1972; MATSUHISA et al., 1979; MATTHEWS et al., 1983). Equilibrium fractionation factors for mineral pairs may then be derived from combining the different mineral-water fractionation data (BOTTINGA & JAVOY, 1975, 1987; CHIBA et al., 1989; CLAYTON et al., 1989; ZHENG, 1991, 1993, 1995; ROSENBAUM & MATTEY, 1995).

Studies of RYE & OHMOTO (1974) present calculations estimating the oxygen isotope composition of water that participated in deposition of metal oxides and silicates to identify the source of the fluid. They show that hydrothermal fluids have diverse origins: meteoric water, trapped sea water, geothermal water, connate formation water as well as metamorphic or magmatic water. These diverse waters may, in certain cases, be distinguished using mineralogic and stable isotopic studies. The water:rock interaction varies between extremes, depending on the water:rock ratio. When the water:rock ratio is large, the δ^{18} O value of the water dominates and the δ^{18} O value of the rock is modified (and vice versa, TAYLOR (1967, 1974)).

It is well known that iron minerals are strongly depleted in ¹⁸O relative to silicate minerals (ZHENG & SIMON, 1991). In general, the δ^{18} O values of magmatic water range between +5 and +10 ‰, the values of metamorphic water have a relatively wide range of δ^{18} O from +5 to +25 ‰ (TAYLOR, 1974). Meteoric water is usually depleted in ¹⁸O relative to SMOW with δ^{18} O values ranging from -20 to 0 ‰ (TAYLOR, 1974; FAURE, 1986). In general, sediments show δ^{18} O values between 5 and 40 ‰ (FAURE, 1986). Less certain is the isotopic composition of seawater in the past, described for example by (CLAYPOOL et al., 1980). Therefore the local oxygen isotope composition of Tyrrhenian carbonates with δ^{18} O between 21 and 36 ‰, were made in this study for Messinian limestones from Tuscany (Table 5.7).

Oxygen isotopes of the cogenetic mineral pairs quartz-magnetite and magnetite-andradite were studied. The temperature-dependent isotope fractionation between pairs of cogenetic minerals provides a sensitive indicator of the temperature of mineral and rock formation (BOTTINGA & JAVOY, 1987; CHIBA et al., 1989; CLAYTON et al., 1989; YAQUIAN & JIBAO, 1993; FORTIER et al., 1995). The oxide-silicate analyses are particularly suitable thermometers as well as indicators for equilibrium/disequilibrium and mineralization processes.

5.2.1 Method

A laser assisted fluorination technique (SHARP (1990) modified by MATTEY & MACPHERSON (1993)) has been used for the determination of ${\rm ^{18}O/^{16}O}$ in microgram quantities of coexisting silicate and oxide minerals.

Focussed high-power laser heat sources, in the presence of a fluorinating agent, allow for oxygen extraction for stable isotope analysis directly from small sample grains. The oxygen of magnetite, and radite and quartz (weight of mineral content ca. 2 mg) was extracted after the method of Sharp (1990) but using F_2 and a platinum sample holder. The released oxygen passed successively over a cold trap and through hot KCl fluorine-getter for cryogenic cleanup and is collected as O_2 on molecular sieve.

The O-isotope ratios are measured on a Finnigan MAT 252 mass spectrometer and the result is normalized relative to NBS - 28 quartz value of 9.64 % against the international standard VSMOW (Vienna Standard Mean Ocean Water):

$$\delta = \frac{({\rm ^{18}O}/{\rm ^{16}O_{sample}} - {\rm ^{18}O}/{\rm ^{16}O_{standard}})}{{\rm ^{18}O}/{\rm ^{16}O_{standard}}} \cdot 1000$$

The oxygen yields were greater than 95 % and the δ^{18} O values are reproducible with an accuracy of ± 0.1 %. The fractionation factor $\alpha_{(X,Y)}$ for the equilibrium isotopic fractionation between X and Y is given by

$$\alpha_{(X,Y)} = \frac{(O^{18}/O^{16})_X}{(O^{18}/O^{16})_Y}$$

where $(O^{18}/O^{16})_X$ is the atomic oxygen isotope ratio for phase X, which is in isotopic exchange equilibrium with phase Y.

The presented mineral - mineral fractionations (of 21 samples and 43 measurements) were calculated from measured values according to methods described by ZHENG & SIMON (1991) and ZHENG (1991, 1993, 1995) for calculating oxygen fractionations in metal oxides.

The values of the thermodynamic isotope fractionation factor of oxygen between the metal oxides and silicates are calculated for temperatures in the range between 0 and 1200°C. The 10^{3} ln α values are obtained for oxygen isotope fractionations between magnetite-quartz, quartz-water and magnetite-water, and magnetite-andradite, magnetite-water and andradite-water, respectively.

5.2.2 Quartz-magnetite

The measured δ^{18} O values for this sensitive thermometer are given in Table 5.2 and 5.3. The isotope ratios of the mineral pairs quartz-magnetite are based on the following coefficients and calculations (ZHENG & SIMON, 1991; ZHENG, 1991)), the resulting temperatures are given by the quadratic equation below:

$$\begin{array}{ll} 1000 \ ln \ \alpha_{qz-H_2O} &= 4.24 \times 10^6 \mathrm{T}^2 - 3.78 \times 10^3/\mathrm{T} - 1.04 \\ 1000 \ ln \ \alpha_{mag-H_2O} &= 3.02 \times 10^6 \mathrm{T}^2 - 12 \times 10^3/\mathrm{T} + 3.31 \\ 1000 \ ln \ \alpha_{qz,mag} &\cong \delta^{18}O_{qz} - \delta^{18}O_{mag} = 1.22 \times 10^6/\mathrm{T}^2 + 8.22 \times 10^3/\mathrm{T} - 4.35 \\ \Delta \mathrm{T}^2 &= 1.22 \times 10^6 + 8.22 \times 10^3 \mathrm{T} - 4.35 \mathrm{T}^2 \\ 0 &= (\Delta + 4.35)\mathrm{T}^2 - 8.22 \times 10^3 \mathrm{T} - 1.22 \times 10^6 \\ \end{array}$$
therefore
$$\begin{array}{l} \mathrm{T}_{1,2} = \frac{8.22 \times 10^3 \pm \sqrt[2]{(-8.22 \times 10^3)^2 - 4(\Delta + 4.35)(-1.22 \times 10^6)}}{2(\Delta + 4.35)} \end{array}$$

The measured isotopic ratios were additionally calculated with coefficients from TAYLOR (1968); ANDERSON et al. (1971); BOTTINGA & JAVOY (1975, 1987) for magnetite and with coefficients from TAYLOR (1967) and CLAYTON et al. (1972) for low quartz (in BOTTINGA & JAVOY (1973)), showing temperature differences up to 50°C.

However, the used method of ZHENG & SIMON (1991) and ZHENG (1991, 1993, 1995) gave

reasonable results in agreement with independent geologic and mineralogic data and is an internally consistent set of fractionation factors. The difference to other thermometers is small and the choice of calibration has no influence on interpretation.

5.2.3 Magnetite-andradite

The resulting δ^{18} O values are given in Table 5.2 and 5.4. The cogenetic mineral pairs magnetite-andradite were calculated on the base and with coefficients of ZHENG (1993) for andradite and ANDERSON et al. (1971) for magnetite as follows

1000 $ln \alpha_{andr-H_2O}$	$= 3.76 \times 10^{6}/\mathrm{T}^{2} - 9.05 \times 10^{3}/\mathrm{T} + 2.52$
1000 $ln \alpha_{mag-H_2O}$	$= -1.81 \times 10^{6} / T^{2} - 3.41$
1000 $ln \alpha_{mag,andr}$	$\simeq \delta^{18} O_{andr} - \delta^{18} O_{mag} = 5.57 \times 10^6 / T^2 - 9.05 \times 10^3 / T + 5.93$
ΔT^2	$= 5.57 \times 10^{6} - 9.05 \times 10^{3} \mathrm{T} + 5.93 \mathrm{T}^{2}$
0	$= (5.93 - \Delta)T^2 - 9.05 \times 10^3 T + 5.57 \times 10^6$

therefore
$$T_{1,2} = \frac{9.05 \times 10^3 \pm \sqrt[2]{(-9.05 \times 10^3)^2 - 4(5.93 - \Delta)(5.57 \times 10^6)}}{2(5.93 - \Delta)}$$

5.2.4 Discussion

The presented calculations enable the estimation of the oxygen isotope composition of water that participated in deposition of metal oxides and silicates and to identify the source of water (RYE & OHMOTO, 1974). Isotope temperatures of involved minerals are approximate values, although the equations made in this study may still be used to illustrate the relationship between the different deposits. However, the reasonable results are in agreement with independent geologic and mineralogic data and gave an internally consistent set of fractionation factors.

The temperatures calculated from mineral formation are given in Table 5.3, 5.4 and Fig. 5.3. Inspection of the isotope ratios reveals that the quartz-magnetite equation in Ginevro and in one sample of the Nuova Zona (Capo Calamita deposit), produces isotope ratios which exclude cogenetic formation and is therefore omitted from Table 5.3. These data are not included in further interpretations, as well as the measurements of $\delta^{18}O_{quartz} = 8.01$ % and $\delta^{18}O_{mag} = 0.48$ % from the Nuova Zona or $\delta^{18}O_{mag} = 4.04$ % from Palazzo (Capo Calamita deposit), which are caused by poor balance and impure material.

Figure 5.3: Calculated temperatures of δ^{18} O (in $\%_0$) of coexisting quartz-magnetite (qz-mag) and magnetite-andradite (and-mag) mineral pairs for several east Elba iron ore deposits, depending on oxygen isotope fractionation. Fractionation factors after ZHENG & SIMON (1991); ZHENG (1991, 1993). Black: Major tectonic lines.

• As expected the iron oxides are strongely depleted in ¹⁸O relative to Fe-bearing silicates and quartz (TAYLOR, 1974).

The δ^{18} O values for coexisting quartz and magnetite indicate a decrease in the ¹⁸O-content in magnetite, while the ¹⁸O-content in quartz increases, with decreasing meta-morphic grade (ZHENG, 1991) and towards the north.

The formerly regarded two-type distinction of Elbanean deposits (Chapter 2, 3, 4) can be confirmed: The Ginevro-type has higher Δ^{18} O ratios for the cogenetic mineral pair magnetite-andradite, than all other deposits (Table 5.4).

The δ^{18} O values within each deposit and the resulting temperatures are consistent. In contrast, the δ^{18} O values of the iron ore deposits are different compared to each other (Table 5.2). The δ^{18} O values reveal a dominance of magmatic fluids as described by Colle et al. (1983); HAYNES & KESLER (1988); CARTWRIGHT et al. (1997) and BUICK & CARTWRIGHT (2000).

- The assumption of isotopic equilibrium between fluid and growing crystal appears to be valid in the crystals analyzed, because the oxygen isotope composition is not variable within each deposit and mineral (Table 5.2).
- The large variety of different host rocks like the carbonate-free Verrucano Formation (Complex III) without skarnization in Rio Albano or the carbonate-dominated wall rocks in the Capo Calamita deposit prove a fluid-controlled or temperature-controlled system.

The little difference in isotopic composition of minerals in the ore or skarn bodies, irrespective the host rocks are gneiss, limestones or sandstones (see Chapter 1), and the isotopic trend is attributed to an increasing oxygen isotope exchange with meteoric water at low temperatures towards the north (about 180°C for Rio Albano). The suggested hydrothermal alteration occurred under oxidizing conditions and caused the formation of specularite.

Small variations in the ${}^{18}O/{}^{16}O$ ratios, the lack of crystal-zonation within each deposit (see Chapter 2, 3) as well as the fluid inclusion data (see Chapter 6), argue against large variations in temperature and in isotopic composition (ONASCH & VENNEMANN, 1995) and for high fluid:rock ratios without wide rock buffering influence (BOWMAN, 1998).

The interaction and transport of meteoric ground water or ocean water through hot igneous rocks with large water:rock ratios or decreasing temperatures of the same fluid can produce an enrichment of ${}^{18}O$ in the water, which is well documented in increased ${}^{18}O_{qz}$ values towards the north (Table 5.2, TAYLOR (1974)).

• The circulating magmatic and meteoric waters contained low initial concentrations of iron. This is compatible with the chemical data of the underlying monzonite with low iron content (around 5 wt %). The characteristics of the ore-bearing fluids, which indicate high NaCl content (Chapter 4, 6), imply solutions carrying large concentrations of iron from the country rocks and involving large amounts of water. The initial δ^{18} O values for whole rock of unaltered andesitic igneous rocks give $6.5 \pm 1 \%$ (TAYLOR, 1974). This are characteristic δ^{18} O values for magmatic rocks and similar to those measured in Capo Calamita and Terra Nera.

The distance to the underlying intrusive body of monzonitic composition in Elba is an observable effect, with increasing δ^{18} O values caused by a larger contribution of meteoric water in greater distance to the intrusion, comparable to calculated δ^{18} O values for

whole rocks and quartz in the Tonopah mining district (Nevada, TAYLOR (1974)) and the Bohemia mining district (Oregon, TAYLOR (1971)).

On the other hand, in an iron oxide dominated deposit, for example in Rio Albano, the infrequent quartz adopts the oxygen isotopic signature of the prevailing iron ore (CLAYTON et al., 1972; BOWMAN, 1998). In the Apuane Alps petrographically similar conditions in iron oxide deposits also give $\delta^{18}O_{qz}$ values around 17 ‰ in a fluid system dominated by magmatic water (COSTAGLIOLA et al., 1990; BENVENUTI et al., 1991; LATTANZI et al., 1994).

Recapitulatory, the rising $\delta^{18}O_{mag}$ values towards the north are interpreted as a result of isotope exchange with an increasing rule of (overall small amounts of) meteoric water.

• Over the comparable deposits Capo Calamita, Rio Marina and Rio Albano for the cogenetic mineral pair quartz-magnetite as well as Ginevro and Capo Calamita for andradite-magnetite, it is to conclude:

The temperature of ore formation and related wall-rock alteration can be estimated in the range between 600°C (magnetite-andradite) for the Capo Calamita deposit and 180°C (quartz-magnetite) in Rio Albano (Table 5.3, 5.4).

Under the fulfilled condition of measuring the same and unaltered mineral generation, the highest temperature within each deposit and mineral pair represents the temperature peak, lower values show a later phase in cooling history. This is well documented in the deposit of Capo Calamita: The highest formation temperature is 600°C for andradite-magnetite and 475°C as cooling temperature. Supposably, the temperature peak was not reached in the Ginevro deposit.

Neverthelass, over the Elbanean deposits the calculated temperatures reveal a gradient to lower temperatures towards the north under the assumption of equilibrium and no alteration after precipitation of ore and skarn minerals. The major deposit in the south, Capo Calamita, outlines the area of highest temperatures and may indicate the presence of a shallow plutonic body.

The deposits of Capo Calamita and Ginevro show a pyrometasomatic formation, whereas the deposit of Rio Albano is of hydrothermal genesis, formed by temperatures below the critical temperature of water (Fig. 5.3).

• Although the sample distribution is not homogeneous, there is a clear suggestion that the area of lowest $\delta^{18}O_{qz}$ values represents both (a) the highest temperature solutions and/or (b) the zone where the most magmatic H₂O was pumped through. Either (a) or (b) is compatible with the suggestion that the hidden pluton is located in the southeast of Elba, because the high temperature plume of upward-moving fluid flow should be centered above the heat source.

5.3 Carbon isotopic study

Fluid flow during metamorphism has wide-ranging effects, including modification of the mineral, chemical, thermal and mechanical properties of rocks along flow path. However, the mechanisms of fluid flow are poorly understood. In contact metamorphic terranes, modification of stable isotope compositions of marbles by fluid infiltration has been measured in order to constrain the fluid fluxes.

The alteration of stable isotopes in marble, resulting from interaction between fluid and rock

Figure 5.4: Isotopic composition of carbon (δ^{13} C) versus oxygen (δ^{18} O) in ‰ for Elbanean marbles depending on their distance to to the skarnified or mineralized contact. The 25 plotted δ^{18} O and δ^{13} C values from the Capo Calamita deposit (Vallone Basso, Vallone Alto, Laveria) and the Rio Marina skarn are listed in Table 5.5. Encircled: Main distribution of less altered Elbanean marbles.

were analysed for east Elba skarn formation. Samples from four localities, of unaltered host rocks as well as profiles depending on their distance to the iron ore contact were collected, where δ^{18} O and δ^{13} C gradients were produced by infiltration of fluids during contact metamorphism.

5.3.1 Method

The oxygen and carbon of calcite were measured after the method from MCCREA (1950) modified by USDOWSKI & HOEFS (1993) with H_3PO_4 . The final results were calibrated against the international standards VSMOW for oxygen and PDB (Belemnitella Americana from the Cretaceous Peede formation, South Carolina) for carbon.

The isotope ratios are calculated as δ values. R_{sample} represents the isotope ratio ${}^{13}\text{C}/{}^{12}\text{C}$ (or ${}^{18}\text{O}/{}^{16}\text{O}$ respectively) of the sample and $R_{standard}$ the ratio of the standards:

$$\delta^{13}C(\%) = \frac{{}^{13}C/{}^{12}C_{(sample)} - {}^{13}C/{}^{12}C_{(standard)}}{{}^{13}C/{}^{12}C_{(standard)}} \cdot 1000$$

Carbon isotopes are measured as CO_2 gas and precision is normally better than 0.1 %. The CO_2 is liberated from carbonates with acid or by thermal decomposition.

The carbon isotope composition in seawater is defined by $\delta^{13}C = 0 \%$, and marine carbonate has a narrow range of values between -1 and +2 ‰.

5.3.2 Results and discussion

The δ^{18} O and δ^{13} C analyses of unskarnified marbles and limestone profiles (depending on their distance to the contact) from the Capo Calamita deposit and the Torre di Rio Marina skarn are documented in Fig. 5.4 and Table 5.5. Oxygen and carbon isotopic data from calcite veins, breccias and interstices between skarn aggregates from several east Elba skarns and iron ore deposits are listed in Fig. 5.5 and in Table 5.6. As a reference, unaltered Messinian marine and lacustrine limestones from Rosignano, Tuscany, are given in Table 5.7.

Integration of isotope analyses (δ^{18} O and δ^{13} C) provides evidence that the fluids were channeled along cracks and grain boundaries within the marble, under the assumption of limited equilibration between rock and fluid (LEWIS et al., 1998).

VÁZQUEZ et al. (1998) proved in a detailed study of stable isotope compositions of host limestones around the El Mochito deposit (Honduras), that the isotope exchange between hydrothermal fluid and limestone produced a strong decrease in δ^{18} O of up to 18 % relative to the background limestone compositions. The decrease of δ^{13} C values up to 4 % is smaller relative to inferred original limestone.

- The δ^{18} O and the δ^{13} C values of unskarnified marbles and limestone profiles depend on the distance to the skarnified or mineralized contact (Table 5.5). This is also clearly supported for similar deposits by studies of JAMTVEIT et al. (1995) and VÁZQUEZ et al. (1998).
- Plots of the δ^{18} O values along three sections show that δ^{18} O values of wall rocks are lowest in the ore zone and increase outward, forming a halo several meters in size. In the same plots, δ^{13} C values of the wall rocks do not show clear systematic spatial variations realtive to mineralization at the scale of sampling. Also, no significant variation was observed in the δ^{13} C values of the unaltered reference samples from Tuscany. There is no correlation between δ^{18} O and δ^{13} C values (Fig. 5.4). Rare inconsistent samples are probably related to irregular ore body outlines, to deposition of post-ore carbonate minerals or to locally lower fluid:rock ratios (STENGER et al., 1998).
- Low values of $\delta^{18}O$ ($\delta^{18}O = 11\text{-}14\%_0$) are observed at the contacts (Table 5.5), whereas the signature of limestones in several meters distance shows an approximation to the unaltered reference samples from the Messinian Rosignano limestones with a mean value of $\delta^{18}O = 25.85\%_0$ for lacustrine limestones and $\delta^{18}O = 35.67\%_0$ for marine limestones (Table 5.7). The high values for the marine limestones are not reached in the low-grade metamorphosed Elbanean limestones, because the $\delta^{18}O$ values depend systematically upon the metamorphic grade (RYE et al., 1976).

The process of silification probably contributed to lower δ^{18} O values in the marble, even in greater distance to the contact, due to high CO₂ pressures from decarbonatization. Another reason could be the loss of CO₂ from decarbonatization probably resulting in ¹⁸O depletion in the marbles (RYE et al., 1976).

• The C isotope fractionation between H₂CO₃ and calcite is strongly temperature dependent. A fluid containing H₂CO₃ as the major carbon species would be buffered towards lower ¹³C/¹²C ratios as compared to a fluid with increasing temperatures (SHEPPARD & SCHWARCZ, 1970; ROBINSON, 1975; VÁZQUEZ et al., 1998). Therefore, significant changes in the C isotope composition of the wall rock may only be expected close to the ore deposit.

In Elba, the high fluid:rock ratios and temperatures were not high enough to allow a significant change in the C isotope composition of the rock. Also, the system of C isotope fractionation is less sensitive than the oxygen system and the underlying plutonic bodies are relativ small. The typical small C isotope halo (VÁZQUEZ et al., 1998) with less than 1 m in diameter, as assumed in Table 5.5, may be related to the chemical composition of the fluid and/or a change in the specification of the C-bearing phases in the fluid with distance from the ore.

• Skarn zones and regions of low δ^{18} O values at iron ore - marble contacts mark channels of fluid flow. The fluid flow was channeled by fractures and contrasts in permeability, which is influenced by the lithology (as described for calcite and quartz enriched zones in general by CARTWRIGHT & BUICK (2000)).

In contrast to oxygen, carbon isotope compositions of the veins, breccias and interstices are generally different and lower than those of the surrounding wall rock (Tables 5.5 and 5.6). This difference tends to be larger in geater distance to the ore deposit, suggesting that the fluid flow became more channelized with distance from the ore deposit (VÁZQUEZ et al., 1998).

This interpretation is compatible with the suggestion that faults and the major N-Sstriking fractures of eastern Elba played an important role in fluid migration and were the focus of fluid flow (DILLES, 1982; SCHULTZ & HAMANN, 1985).

Chapter 6

Fluid inclusion studies

6.1 Introduction

Much of the skarn fluid inclusion (FI) literature has been summarized by KWAK (1986) and KWAK & BROWN (1986). MEINERT (1992) presented FI homogenization temperatures up to 750°C. In general, worldwide, FI data fall into the temperature range between 300°- 550°C. This is consistent with the relatively shallow geological settings inferred for the Elbanean skarn deposits.

The salinity in most fluid inclusions (FIs) in skarn minerals is high. Observed daughter minerals in FIs of skarn minerals include CaCl₂, FeCl₂, NaCl, KCl, CaCO₃, CaF₂, C, NaAlCO₃(OH)₂, Fe₂O₃, Fe₃O₄, AsFeS, CuFeS₂, and ZnS. KESLER et al. (1986) and HAYNES & KESLER (1988) describe systematic variations in NaCl : KCl : CaCl₂ ratios of FIs from different skarns reflecting different fluid sources and varying degrees of mixing of magmatic, connate, and meteoric fluids. In general, magmatic fluids have KCl > CaCl₂ whereas CaCl₂rich fluids appear to have interacted with sedimentary wall rocks (KWAK & TAN, 1981b). FIs can provide direct evidence for the presence of CO₂ (both liquid and gas), CH₄, N₂, H_S and other gases in hydrothermal fluids. Studies of gas phases and immiscible liquids in FIs typically show a dominance of CO₂, a critical variable in skarn mineral stability. Although no comparative studies are available, it appears that CH₄ is slightly more abundant than CO₂ in reduced systems (DRUMMOND & OHMOTO, 1979, 1985; GERSTNER et al., 1989), whereas CO₂ is more abundant than CH₄ in more oxidized systems such as copper and zinc skarns (MEGAW, 1988).

Studies of FIs in different skarn minerals are particularly useful to document the temporal and spatial evolution of skarn-forming fluids and to correlate chemical changes, experimental and thermodynamic data (e.g. KWAK & TAN (1981a,b); MEINERT (1987)). FIs also provide direct evidence for the temperature and salinity shift in most skarn systems between prograde and retrograde skarn events. For example, most garnet- and pyroxene-hosted FIs from iron skarns show homogenization temperatures in the range between 370° and 700°C and 300°-690°C, respectively, and salinities up to 50 wt% NaCl_{equiv.}; whereas FIs in retrograde epidote and quartz from crosscutting veins have homogenization temperatures in the range between 100°- 250°C and salinities of less than 25 wt% NaCl_{equiv.} (MEINERT, 1987).

CAMPBELL & ROBINSON (1987) and CAMPBELL (1991) introduced infrared (IR) microscopy to the study of FIs in some opaque ore minerals. This method allows observations in the near

infrared light wavelength range from 0.8 - 2.5 μ m (= 800 - 2500 nm). FI studies in hematite (and Mn oxides) from different deposits in the Kalahari Manganese Field (South Africa) are published by LÜDERS et al. (1999).

6.2 Previous work on Elba skarns

The concentration process by pyrometasomatism for the first magnetite generation indicates temperatures of 450°C in Ginevro (determined in experiments from GILBERT (1966) in DI-MANCHE & BARTHOLOMÉ (1969); DIMANCHE (1971)), specified by the oxide stabilities of POPP et al. (1977a,b). For Rio Marina hematite, DESCHAMPS et al. (1983b) estimated homogenization temperatures of fluid inclusions between 350 and 200°C (in quartz). Syn- to post-tectonic growth of the youngest, lamelliferous generation of hematite (specularite) occurred at low formation temperatures between 280 and 250°C, based on fluid inclusion studies (DESCHAMPS et al., 1983b; LIPPOLT et al., 1995). This generation is present in all northern deposits (Terra Nera, Rio Marina and Rio Albano).

6.3 Methods and basis of infrared microscopy

FIs in hematite and pyrite were studied using an Olympus-BHSM infrared microscope combined with an U.S.G.S. heating/freezing system at the Geoforschungsinstitut Potsdam. This combination of microscope and gas-flow heating/freezing system allows measurements in the temperature range between -190 and 600°C. The infrared image is transmitted to a monitor by an infrared TV camera. The resolution of the IR camera can be enhanced up to 2.5 μ m by the use of a high-resolution IR-tube. For FI studies long-working distance IR objectives with magnifications up to 80x are used. For calibration, Synflinc standards and natural inclusions in transparent minerals were measured with the IR equipment and in transmitted light. The thickness of doubly polished thick sections of hematite and pyrite was chosen between 80 and 100 μ m.

For this study 42 thick sections of hematite and pyrite from the deposits of Capo Calamita, Terra Nera, Rio Marina and Rio Albano were prepared. 3 samples of pyrite (pyrite II, see Chapter 2) from Terra Nera and Rio Marina and 17 hematite samples (hem II and III, Chapter 2) were chosen for infrared investigation.

The method of infrared microscopy was chosen to characterize internal texture, to test the age relations for hematite generations and to obtain information about the composition of mineral forming fluids and their temperature of formation. Unfortunately, most hematites from the deposits are opaque. Incomplete martitization and alteration are probable reasons for the distinct differences in transmittance (Fig. 6.1, 6.2 and 6.3 e). The analyses documented in the following are tabulated in the Appendix.

6.4 Results

During heating the minerals, some samples became opaque prior to homogenization of the FIs (mainly from the Capo Calamita and the Rio Albano deposit), caused by a shift of band gap to higher wavelengths (LÜDERS & ZIEMANN, 1999). This decreasing IR transparence

RESULTS

Figure 6.1: Fourier transmission infrared (FTIR) spectra showing differences in infrared transmittance versus wavelengths of hematite and magnetite from different locations (after LÜDERS, unpubl. data).

with progressive heating was compensated by boosting the sensitivity of the IR camera, and measurements of the homogenization temperatures were partly possible.

6.4.1 Pyrite

The IR transparece of pyrite strongly depends on the chemical composition and trace element content. Pyrite that contains an elevated amount of trace elements (e.g. As) is opaque for near infrared radiation up to $\lambda = 1.9 \ \mu m$ (RICHARDS & KERRICH, 1993a). On the other hand, pyrite with low trace element content can exhibit up to 40 % IR transmittance at 1.8 to 2.5 μm and is suitable for FI studies (LÜDERS & ZIEMANN, 1999).

The analyzed pyrite samples from Terra Nera (ES 36, ES 69) and Rio Marina (V 6) deposits show similar and relatively good IR transmittance varying between 1 and 11.5 % in the spectral range of the used camera. Therefore, a small trace element content is assumed for the analyzed pyrite of the second generation (Chapter 2).

Elongated to oval FIs with lengths up to 35 μ m occur in pyrites of the Terra Nera and the Rio Marina deposit. These fluid inclusions are mostly opaque, showing a high IR absorption. The problem is based on frequently occurring cracks. The cracked pyrite crystals result in scattered radiation, making the recognition of FIs impossible. IR microscopy applied on pyrite as described by RICHARDS & KERRICH (1993a) and LÜDERS & ZIEMANN (1999) showed that pyrite is not suitable for IR microthermal investigations.

6.4.2 Hematite

The analyzed hematites from the deposits of Terra Nera, Rio Marina and Rio Albano show different IR transmittance (Fig. 6.2). The sizes of FIs in hematite range between 10 and 450

 μm (Fig. 6.3).

Figure 6.2: Fourier transmission infrared (FTIR) spectra showing the differences in the infrared transmittance versus wavelengths of hematites from the Terra Nera (ES 37) and the Rio Marina deposit (M 233).

6.4.2.1 IR transmittance

All studied samples from the Terra Nera deposit show good IR transmittance, while the Rio Marina samples are partly opaque. The Rio Albano hematites contain several primary and numerous secondary fluid inclusions of variable (mostly small) sizes. However, only little IR transparent regions are contained in the studied samples (Fig. 6.3 f). Due to alteration of the sample material - the mines of Rio Marina and Rio Albano are abandoned since ca. 20 years - the IR transmittance decreases. Therefore, a fresh sample from the Rio Marina deposit (kindly provided by the Humboldt-University Berlin) which shows a good IR transmittance was chosen for comparison. The differences in IR transmittance are probably caused by incomplete replacement processes (e.g. martitization, see Chapter 2) or the mineral acts as IR activated semimetal, adsorbing IR light (LÜDERS & ZIEMANN, 1999).

The different IR transparence is documented for the Terra Nera and the Rio Marina deposit in Fig. 6.2: Sample ES 37, from the Terra Nera deposit, shows an IR transmittance of up to 40 % in the spectral range between 1.0 and 1.4 μ m. In contrast, a sample from the Rio Marina deposit (M 233) only displays 12 % IR transmittance.

6.4.2.2 Texture of fluid inclusions

The detailed studied samples from Terra Nera and Rio Marina contain FIs of variable sizes and liquid/vapor ratios (Fig. 6.3 a-e): Several samples exhibit crystal zonation (Fig. 6.3 a,e) and lamination. In some cases FIs are arranged along or within this lamination (ES 69). Similar FIs occur isolated within hematite crystals, and therefore, they appear to be of primary origin (ROEDDER, 1984); Fig. 6.3 b,c). Rarely liquid-rich, two-phase FIs are observed.

In some samples liquid-rich and vapor-rich inclusions are connected by thin necks (Fig. 6.3

RESULTS

d), indicating that these secondary inclusions are formed by necking-down. Secondary FIs occur mostly along trails parallel to the optical pressure-lamination, in samples of the Terra Nera and rarely in the Rio Marina deposit. This lamination is locally roughly oriented perpendicular to the direction of zonation (Fig. 6.3 e). No inclusion trails were found along the zonation (Fig. 6.3 a), indicating trace element zonation below the detection limit (as described in Chapter 3), instead of typical crystal growth zonation.

FIs are arranged along healed cracks in the Terra Nera sample ES 69, partly brittly deformed and sheared. The FIs occur mostly along trails or in clusters unsystematic to oriented planes. These secondary inclusions do not provide information about the composition of the mineralforming fluids and the temperature of formation, but they provide indications of a later, secondary fluid overprint (RICHARDS & KERRICH, 1993b).

Isolated FIs in hematite crystals from the Rio Marina deposit reach 450 μ m in length (Fig. 6.3 b,c). They are assumed to be of primary origin (ROEDDER, 1984), because they are isolated, without necking-down and away from any alteration, veins or weathering. They show different characters: Two-phase FIs with liquid/vapor ratios of about 9:1 are observed and, furthermore, FIs with irregular shapes and high reliefs occur (Fig. 6.3 b,c).

6.4.2.3 Microthermometric studies

Cryometric studies of hematite-hosted FIs (from the Terra Nera and the Rio Marina deposit, Table 6.1), show low first melting temperatures (T_e) in the range between -62° and -50°C (mean -54°C). The phase transitions upon further heating are difficult to observe, due to the high relief of the inclusions (Fig. 6.3 b). Efficient melting of a frozen (ice or hydrate) phase at temperatures between -31.4 and -27.5°C (final melting point $T_{m,ice1}$) was mostly observed. In some inclusions, additional melting of a second phase ($T_{m,ice2}$, Table 6.1), with temperatures between -11.8 and -9.9°C, was observed. DAVIS et al. (1990) interpret this phenomenon as metastable phase-melting or resulting from iron chloride in the fluid phase (KWAK & BROWN, 1986).

In FIs (ES 37, ES 38, hub 3) with melting temperatures between -27 and -25.6°C, no secondary phase transition occurred upon further heating. POTTER et al. (1978) calculated correlations between different salinities and freezing points of aqueous sodium chloride solutions. He demonstrated that the fluid-forming solution is saturated with respect to NaCl at a melting point of -20.81 ± 0.03 °C. Thus, the eutectic found by POTTER et al. (1978) at 23.2 wt% NaCl concentration, lies at the metastable extension of the freezing point. In this study, the final melting points plot around -28°C, indicating an additional liquid phase (e.g., in colloidal state) in the hematite-forming fluid or metastability (DAVIS et al., 1988, 1990). The fluid is not supersaturated, because no salt precipitates in the FIs.

Cryometric measurements of primary FIs from the Rio Marina deposit (M 233, Fig. 6.3 c) did not show any phase transition due to the high relief of the FIs.

Secondary FIs from the Rio Marina deposit (M 233) show final melting of ice in the range between -18 and -17.6°C (mean -17,8°C).

6.4.2.4 Homogenization temperatures

The homogenization temperatures of FIs in hematites from the two analyzed deposits show mineral formation temperatures without significant differences. The range of homogenization temperatures (for primary FIs) for samples from the Terra Nera deposit were between 299

Figure 6.3: Sequence of transmitted IR light microphotographs of hematites from Elba Island. Rio Marina deposit: a) growth zones in hematite (hub); b) characteristic two-phase fluid inclusion with irregular shapes and high relief (hub 2); c) rare primary two-phase fluid inclusion (M 233). Terra Nera deposit: d) characteristic "necking down" of two-phase fluid inclusions (ES 36); e) zoned hematite with patchy IR transparency. The zonation is roughly oriented perpendicular to the lamination (ES 45). Rio Albano deposit: f) secondary FIs oriented along a trail in lamellar hematite (R 208).

Table 6.1: Summary of mean microthermometric data (in °C) of primary fluid inclusions in hematites from the Terra Nera (ES) and the Rio Marina (Hub, M) deposit. Abbreviations: T_e : first ice melting temperature, $T_{m,ice}$: final ice melting temperature, T_h : homogenization temperature, n.d.: no data.

and 331°C, these from the Rio Marina deposit range between 300 and 324°C (Table 6.1). The similarity of homogenization temperatures for the two deposits (mean $T_h = 319$ °C) suggest a hematite (hem II) formation in the Terra Nera and the Rio Marina deposit contemporaneously from a similar fluid. The mean values of the Terra Nera ($T_h = 323$ °C) the Rio Marina deposit ($T_h = 315$ °C) show the same temperature within the error limits. Secondary FIs in hematite from the Rio Marina deposit gave homogenization temperatures of 112°C (mean). RUGGIERI & LATTANZI (1992) analyzed FIs in quartz, beryl and tourmaline from the Monte Capanne pegmatites, western Elba. The earliest recorded liquid rich, biphasic fluids gave homogenization temperatures of 323°C to 388°C and low salinities of 0.7 - 7.7 wt% NaCl_{equiv}. Secondary trails with homogenization temperatures of 189°C - 223°C and low salinities indicate an increasing contribution of meteoric fluids. These FIs differ clearly from the above described results of the east Elba ore forming fluid.

The assumed high salinity for Elbanean fluids causes low values of f_{O_2} as well as low X_{CO_2} , (BELKIN et al., 1983; CAMPBELL, 1991), corresponding to the results from geochemistry of the Elbanean skarns (see Chapter 4.6). The primary FIs from the east Elba ore deposits have higher salinities in comparison with FIs from other, similar magmatic provinces: COSTAGLI-OLA et al. (1990) analyzed barite, quartz and fluorite of a barite-pyrite-iron oxides deposit (2-3 bar), Monte Arsiccio (Apuane Alps). Similar to the Pollone deposit, analyzed by BEN-VENUTI et al. (1986), the salinities are constantly lower (below 14 wt%). Another similar and sulfide dominated deposit formed in the Apennine event (at 2 kbar, Maremma, Tuscany (BELKIN et al., 1983)) shows homogenization temperatures in two-phase, primary inclusions in sphalerite (of the ore bodies) of 200°C and a maximum salinity of 13 wt% NaCl_{equiv}.

6.5 Atomic Absorption Spectroscopy

Atomic Absorption Spectroscopy (AAS) is another common method to specify the element composition of fluid inclusions.

The NaCl: KCl: CaCl₂ ratios of fluid inclusions reflect different fluid sources and varying

Table 6.2: Element content (in ppm) of calcium (Ca), magnesium (Mg), potassium (K) and sodium (Na) of fluid inclusions in hematite (hem), specularite (spec) and magnetite (mag) from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano made by atom-absorption-spectrometry. Bold: Major iron ore generation (see Chapter 2). Reference analyses of synthetical quartz grains and H_2O_{bidest} are also listed.

degrees of mixing of magmatic, connate and meteoric fluids (HAYNES & KESLER, 1988). In general, magmatic fluids have $KCl > CaCl_2$, whereas $CaCl_2$ -rich fluids appear to have interacted with sedimentary wall rocks (KWAK & TAN, 1981b).

6.5.1 Method

In atomic absorption spectroscopy (MAXWELL, 1968; MCLAUGHLIN, 1977; WELZ, 1983) a solution of the sample is sprayed into a flame-less graphite furnance, causing the compounds present in the solution to dissociate into their constituent atoms. The heating-rate (by an electric current around 400 A and up to 3000°C) and the temperature-dispersion in the graphite furnance are decisive for the quantitative atomization of an element. Typical concentrations range in the low mg/l range.

The method is based on the absorbtion of radiation of element-specific wavelength, which results in well-defined spectra. Each element needs a different lamp to produce its characteristic radiation. The total amount of light absorbed is measured and, by comparison with the standards, element concentrations can be calculated. The analysis ideally requires several microliter sample material. The detection limit for the graphite furnance AAS (Analyst 300 Perkin-Elmer) is 0.1 ppm for Ca, 0.01 ppm for Na and Mg and 0.05 ppm for K.

Twelve samples from different deposits were measured, together with reference analyses of H_2O_{bidest} and of fire-dried synthetical quartz grains to evaluate the abrasion of the used agatemortar. 5 grams iron-oxide were crashed for 4 minutes in 10 ml of H_2O_{bidest} to solubilize the element content of the fluid inclusions.

6.5.2 Results

Element content of calcium (Ca), magnesium (Mg), potassium (K) and sodium (Na) of fluid inclusions in hematite and magnetite from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano are listed in Table 6.2. The element content of H_2O_{bidest} corresponds to the mortar abrasion and is corrected within calibration. In the reference samples of synthetical

Table 6.3: The NaCl : KCl : $CaCl_2$ ratios of fluid inclusions in hematite, specularite and magnetitefrom the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano, based on Table 6.2.

Figure 6.4: Cation compositions of fluid inclusions in hematite, specularite and magnetite from the deposits of Ginevro, Terra Nera, Rio Marina and Rio Albano plotted in terms of major cation relations. The numbers refer to AAS-measurements listed Table 6.2.

quartz, sodium (between 4.2 ppm and 1.0 ppm), potassium (between 3.9 ppm and 2.2 ppm) and calcium (between 2.9 ppm and 1.1 ppm) diversify, caused also by mortar abrasion or by primary variety of quartz grains.

One sample of the Terra Nera deposit (ES 36, Table 6.2) shows an insoluble residue, which could not be educed and possibly affects the resulting values.

Note the highly variable content of sodium without an interpretable system. The small grain size and the intergrowth of different iron oxides and/or different generations exclude the preparation of pure monomineralic material. Additionally the unknown but highly visible (Fig. 6.3) content of secondary fluid inclusions within the samples culminate basically in the disability of interpretation.

Overall the small content of calcium for all deposits is inline with comparable deposits described above by KESLER et al. (1986) and HAYNES & KESLER (1988).

Nevertheless the normalized cation compositions of FIs (Table 6.3, Fig. 6.4) document the relations between the different deposits and mineral generations. Sample R 216 from the Rio Albano deposit is dominated by the youngest iron ore generation, specularite, containing the highest NaCl₂ and the lowest CaCl₂ and KCl content (Table 6.4). Sample ES 69 from the Terra Nera deposit also consists of remarkable amounts of specularite, resulting in high NaCl₂ and low CaCl₂ and KCl content. These high NaCl₂ content shows propably the increasing effect on seawater at the Messinian salinity crisis (FLECKER & ELLAM, 1999; KRIJGSMAN et al., 1999) at the last Elbanean ore forming stage. Older magnetite generations yielded inclusion-derived salts with lower NaCl₂ content (Fig. 6.2 and 6.4: 1, 2, 4, 5).

The NaCl:KCl:CaCl₂ ratios of fluid inclusions (Fig. 6.3) reflect a magmatic fluid with KCl > CaCl₂ for the Ginevro and the Terra Nera deposit (Table 6.3), whereas in Rio Marina and Rio Albano CaCl₂-rich fluids (CaCl₂ > KCl) appear to have interacted with sedimentary wall rocks (KWAK & TAN, 1981b).

By circulation of the hydrothermal solutions, crystallization of Fe calc-silicate minerals, and dissolution of available calcite, pore space is produced. The largest part of the CaCl₂ present in the fluid is believed to be directly proportional to the amount of Fe calc-silicate crystallization and the amount of fluid circulation in the convective system. If circulation is sufficiently slow, then all Fe chloride will be consumed (if enough silica is present) and CaCl₂ will reach a maximum value (KWAK & TAN, 1981b; DIPPLE & GERDES, 1998; BOWMAN, 1998), which does not correspond in Elba.

The crystallization of pyroxene, garnet and quartz (see Chapter 2, 3) involves little Na or K and as a consequence the NaCl:KCl ratios are mostly unaffected. The amounts of NaCl and KCl will relate to such processes as boiling, dilution, and possible changes in the composition of the primary fluids (KWAK & TAN, 1981b). After the end of andradite and amphibole crystallization and the precipitation of specularite (see Chapter 2, 3), less CaCO₃ was available for solution and the fluid compositions indicate less CaCl₂ (Table 6.3, Fig. 6.4).

The compositions of CaCl₂-bearing FIs plotted in Fig. 6.4 with additional textural, temperature and other data reported before, can be explained by two factors: These are dilution and the degree to which Fe calc-silicate-generating reactions (which cause the solution of CaCO₃ to produce CaCl₂) have occurred. When most of the consumable CaCO₃ was used up, solution composition changed towards CaCl₂ free composition (Table 6.3, Fig. 6.4). The slight shift toward NaCl (Fig. 6.4) could have been caused by the crystallization of amphibole having high K:Na ratios at this time (see Chapter 3). The resulting solutions would be slightly depleted in K relative to Na (Table. 6.3).

CONCLUSIONS

6.6 Conclusions

- Pyrite (py II, see Chapter 2) from the Terra Nera and the Rio Marina deposit contain small amounts of trace elements (RICHARDS & KERRICH, 1993a). The FIs in this pyrite show high IR absorption and are not suitable for IF microthermometric investigations.
- Most hematites within the Elbanean deposits are IR-opaque, probably because of incomplete martitization as well as alteration. The FIs in hematite from the Rio Albano deposit are too small for microthermometric studies and show little IR transparence. Thus, only hematite (hem II, see Chapter 2) from the deposits of Terra Nera and Rio Marina has been analyzed by infrared microscopy.
- The final melting point $(T_{m,ice1})$ around -28°C, as well as the occurrence of an additional liquid (e.g., in colloidal state) in the hematite-forming fluid of high salinity shows metastable phase-melting and iron chloride in the fluid phase (KWAK & BROWN, 1986) for both deposits. The higher the fluid salinity, the higher the solubility of iron in the fluid. But the inclusions are too small, and no additional (crystalline or liquid) phase can be recognized within the FIs.

In some primary inclusions, additional melting of a second phase $(T_{m,ice2})$, with temperatures in the range between -11.8 and -9.9°C, was measured. DAVIS et al. (1990) interpret this phenomenon as metastable phase-melting or as a result of occurrence of iron chloride in the inclusions.

- Secondary FIs of the Rio Marina deposit show final melting of ice at temperatures of -17.8°C (mean), corresponding to 20.8 wt% NaCl in the fluid (POTTER et al., 1978). These secondary inclusions in hematite show homogenization temperatures of about 112°C (mean).
- The similarity of homogenization temperatures for the Terra Nera ($T_h = 323^{\circ}C$) and the Rio Marina deposit ($T_h = 315^{\circ}C$) let assume that the hematite (hem II) formation occurred contemporaneously and from a similar fluid.
- The primary FIs from the east Elba ore deposits show characteristic higher salinities in comparison with analyses from other, similar magmatic provinces. This may be explained by marine sediments in the sedimentary succession of evaporizing basins, or as an example for the Messinian salinity crisis (CLAUZON et al., 1996; KRIJGSMAN et al., 1999).
- The assumed high salinity for Elbanean fluids causes low values of f_{O_2} as well as low X_{CO_2} , (Belkin et al., 1983; CAMPBELL, 1991), corresponding to the results from geochemistry of Elbanean skarns (see Chapter 4.6).
- Secondary FIs in hematite from the Rio Marina deposit gave homogenization temperatures of 112°C, indicating an increasing contribution of meteoric fluids in the subsequent hydrothermal stage.
- The unknown but visible (Fig. 6.3) content of secondary fluid inclusions within the samples complicates the interpretation of the atomic absorption spectroscopy data. In addition, a small grain size and the intergrowth of different iron oxides and/or different generations exclude the preparation of pure monomineralic material. Overall, the atomic

absorption spectroscopy attests a relatively small content of calcium for all deposits, whereas $CaCl_2$ -rich fluids appear to have interacted with sedimentary wall rocks (KWAK & TAN, 1981b).

• The NaCl:KCl:CaCl₂ ratios of fluid inclusions reflect a magmatic fluid with KCl > CaCl₂ for the Ginevro and the Terra Nera deposit, whereas in Rio Marina and Rio Albano slightly CaCl₂ enriched fluids appear to have interacted with sedimentary wall rocks. High NaCl₂ content of specularite shows probably the infiltration of high saline marine brines (Messinian salinity crisis) at the last Elbanean ore forming stage. Older magnetite generations yielded inclusion-derived salts with lower NaCl₂ content. The crystallization of pyroxene, garnet and quartz (see Chapter 2, 3) involves little Na or K and as a consequence the Nacl:KCl ratios are mostly unaffected. The amounts of NaCl and KCl will relate to such processes as boiling, dilution, and possible changes in the composition of the primary fluids (KWAK & TAN, 1981b). After the end of andradite and amphibole crystallization and the precipitation of specularite (see Chapter 2, 3), less CaCO₃ was available for solution and the fluid compositions indicate less CaCl₂. The compositions of CaCl₂-bearing FIs can be explained by dilution and the degree to which Fe calc-silicate-generating reactions (which cause the solution of $CaCO_3$ to produce $CaCl_2$) have occurred. When most of the consumable $CaCO_3$ was used, solution composition changed towards CaCl₂ free composition. The slight shift toward NaCl could have been caused by the crystallization of amphibole having high K:Na ratios at this time (see Chapter 3). The resulting solutions would be slightly depleted in K relative to Na.

114

Chapter 7 Conclusions

7.1 Iron ore deposits

In agreement with DIMANCHE & BARTHOLOMÉ (1969); DIMANCHE (1971); JENKS (1975); ZUFFARDI (1990); LIPPOLT, WERNICKE & BÄHR (1995), one can conclude that the primary iron source are late Paleozoic to Triassic sediments, from which Fe was mobilized during hydrothermal activity driven by late Miocene magmatism.

The Capo Calamita deposit, close to the pluton, shows the highest mineral diversity of ore and skarn mineralization. Lamellar hematite I from the Capo Calamita deposit (and rarely from Terra Nera) can be classified as oldest oxide generation. Mushketovitization and martitization are described for Elbanean ore deposits for the first time. Fig. 7.2 presents a model of ore formation and a simplified profile of the environment of Capo Calamita.

There are only small differences in the chemical composition of the silicates and oxides between East Elbanean deposits, indicating large amounts of iron- and calcium-rich fluid influx. The small trace element variations of iron oxides are caused by different host rocks. The minor trace element variance within the silicates is only disrupted by pyroxene: Salitic mineral-cores occur in Ginevro and Sassi Neri, ferrosalites in mineral-rims of Ginevro and Sassi Neri and only ferrosalite in Capo Calamita and Rio Marina.

The decrease of temperature towards the north, towards younger oxide generations and less content of trace elements prove two types of iron ore deposits, according to the chemical and isotopic composition: The magnetite-bearing deposits of Ginevro and Sassi Neri and the hematite-bearing deposits of Capo Calamita, Terra Nera, Rio Marina and Rio Albano towards the north. The S-N temperature gradient with increasing distance to the shallow intrusion is supported by the mineral assemblages, the formation temperature and the isotopic composition.

The paragenetic variance is getting smaller towards the north. The ore bodies represent mineral assemblages of lower formation temperature (see Chapter 3, 4, 5) and sedimentary structures have survived the hydrothermal activity. Pyrite dominates the Rio Marina deposit, specularite the Rio Marina and the Rio Albano deposits, while cassiterite- and silicon-bearing magnetites are missing (Chapter 3, Table 3.7). Due to increasing distance from the intrusion, skarn is uncommon; in Rio Albano no skarn exists.

Silicon-bearing magnetite indicates fast formation under disequilibrium conditions (SHIMAZAKI, 1998; SHCHEKA et al., 1977) for Capo Calamita and Terra Nera (Table 2.1).

Figure 7.1: The island of Elba with emplacement of the Monte Capanne granodiorite into a series of previously regionally metamorphosed gneisses, in marbles and marble-bearing schists. The tectonic Complexes I - V are classified after TREVISAN (1950). The dashed line outlines the supposed position of the Porto Azzurro pluton.

Figure 7.2: a) Model of late Miocene shallow magmatic-hydrothermal ore formation with schematic precipitation and presumed surface. Arrows indicate the thermal convection, representing the fluid transport. b) Simplified profile of the expected environment of the Capo Calamita deposit fractures, older N-S striking faults in the Calamita Schists, and the parauthochtonously overlying slices of mainly mineralized Upper Triassic "*calcare cavernoso*" (Chapter 1, Fig. 1.4). Scale: Horizontal distance ca. 2 km, vertical distance ca. 1 km (?).

The Zuccale Detachment Fault (ZDF) separates the underlying Calamita Schists (including Ginevro and Sassi Neri) from the overlying series, containing the other ore deposits. Within the ZDF only the youngest ore generation, lamellar specularite, occurs as syn- to postkine-matic formation.

SKARNS

For this study, theoretical phase diagrams of the hematite-magnetite-pyrite buffer, based on experimental data from SHI (1992), delimit the composition of the involved fluid phase (see Chapter 4). The path along the reaction equilibrium was reconstructed for the Terra Nera deposit for a simplified one-phase cooling process (Fig. 4.14).

The similarity of homogenization temperatures for the Terra Nera ($T_h = 323$ °C) and the Rio Marina deposit ($T_h = 315$ °C) indicate the hematite (hem II) formation contemporaneously and from a similar fluid. The primary fluid inclusions from the east Elba ore deposits show characteristic higher salinities in comparison with analyses from other, similar magmatic provinces (Chapter 6), probably caused by marine host rocks in the succession of evaporizing basins or related to brines formed during the Messinian salinity crisis (CLAUZON et al., 1996; KRIJGSMAN et al., 1999).

The assumed high salinity for Elbanean fluids causes low values of f_{O_2} as well as low X_{CO_2} (BELKIN et al., 1983; CAMPBELL, 1991), corresponding to the geochemical results from Elbanean skarns (see Chapter 4.6). Secondary Fluid inclusions in hematite from the Rio Marina deposit gave homogenization temperatures of 112°C, indicating an increasing contribution of meteoric fluids in the subsequent hydrothermal stage.

Atomic absorption spectroscopy analysis attests a small content of calcium for all deposits. The higher NaCl₂ content of specularite shows probably the infiltration of high saline marine brines (Messinian salinity crisis) at the last Elbanean ore forming stage. The NaCl:KCl:CaCl₂ ratios of fluid inclusions reflect a magmatic fluid with KCl > CaCl₂ for the Ginevro and the Terra Nera deposits, whereas in Rio Marina and Rio Albano CaCl₂-rich fluids appear to have interacted with sedimentary wall rocks. After the end of andradite and amphibole crystallization and the precipitation of specularite (see Chapter 2, 3), less CaCO₃ was available for solution and the fluid compositions indicate less CaCl₂.

LIPPOLT et al. (1995) dated the late-stage minerals from the Rio Marina deposit. The hematite samples define a (U + Th)-⁴He age of 5.39 ± 0.5 Ma and paragenetic adularia gives a mean age of 5.32 ± 0.1 Ma using the K/Ar method. Both minerals fix the end of the Elbanean iron ore mobilization and formation.

7.2 Skarns

The Elbanean skarns can be classified as shallow and altered exoskarns, containing Ca- and Fe-rich and hydroxyl-bearing silicates. The contact pneumatolytic replacement deposits (EIN-AUDI et al., 1981) and skarn areas are mostly unzoned, which indicates relatively fast formation conditions. A Fe- and Ca-rich composition is suggested for the fluid influx (Chapter 2 and 3). The metasomatic minerals did not grow under isochemical conditions, as would be expected for skarn formation processes.

The Triassic to Jurassic limestones are best candidates as sources of the involved calcium. In the Ginevro and the Sassi Neri deposits, no primary carbonate is found, but carbonate lenses are described in the geological profiles of the "Società delle miniere della comune di Rio Marina" and by DIMANCHE (1974a) from subsurface outcrops.

In general, an overlap of skarn and ore formation with two main formation periods can be distinguished within the Capo Calamita deposit (Fig. 2.5, 2.8):

- 1) Ferrosalite, andradite, magnetite II, ilvaite, hematite II, quartz
- 2) Pyrrhotite, ferro-actinolite, ilvaite, magnetite III, epidote, calcite, quartz

The exoskarns are altered by circulating fluids. Supercritical gas discharge due to pressure relief typically caused both vaporization and distillation processes in the wall rock (described generally by EINAUDI et al. (1981)). In the Capo Calamita deposit pyroxene is altered to amphibole (uralite) and garnet, presumably by water-rich fluids, as generally observed by KOSTYUK & SOBOLEV (1969). The temperature of uralite formation from the Capo Calamita deposit did not exceed 480°C (at $P_{H_2O} = 1$ kbar, after BOYD (1959)). The contact metamorphic mineral ilvaite acts as an index mineral (Chapter 4): Marginally dissolved ilvaite crystals included in pyrite from the Rio Marina deposit were formed by relatively high f_{S_2} . The minimum level for formation of the surrounding pyrite gave f_{S_2} around 10⁻⁴ bar (at 2 kbar and below 527°C), after GUSTAFSON (1974).

For the reaction and radite-hedenbergite in Elba f_{O_2} between 10⁻³³ bar and 10⁻¹⁸ bar are relevant, estimated according to the maximum temperature appraisals of DIMANCHE & RUIZ (1969), DIMANCHE (1971) and DÜNKEL (2001). The oxygen fugacity for the cogenetic mineral pair and radite and magnetite can also be restricted to f_{O_2} between 10⁻¹⁸ bar and 10⁻³³ bar at 500°C and 1 kbar (REDHAMMER et al., 2000) for the Capo Calamita deposit. The chemical composition of ilvaite is uniform with an upper temperature limit of ilvaite formation of 430°C at 0.5 kbar or 460°C at 1 kbar (ERNST, 1966).

Activities representative for the deposits of Ginevro and Capo Calamita are $a_{and} = 0.8$, $a_{cc} = 0.9$, $a_{Fe-act} = 0.06$ and a_{hed} between 0.8 and 0.05, resulting in the mineral reactions shown in Table 4.1 and Table 4.2. Due to the thermodynamic database of BERMAN (1988) and GHIORSO & EVANS (2002) isothermic log f_{O_2} - log a_{CO_2} diagrams were calculated: Assuming a temperature of 400°C, the formation of andradite (Fig. 4.17) refers to a fluid phase with log $a_{CO_2} < -1$ ($a_{CO_2} < 0.1$). For 600°C andradite points to a higher CO₂ activity with log $a_{CO_2} < -0.1$ ($a_{CO_2} < 0.8$).

The carbonate-bearing samples from the Capo Calamita deposit indicate higher f_{O_2} and higher a_{CO_2} values and give minimum values for $a_{hed} = 0.05$. Salite-bearing samples of Ginevro were less oxidized and show lower a_{CO_2} values (Fig. 4.17).

7.3 Isotopic studies

Sulfur isotopic studies on a variety of sulfide minerals (pyrite, pyrrhotite and chalcopyrite) from Elbanean deposits indicate a very narrow range of δ^{34} S values from 1.7 to 12.1 %₀ (relative to CDT, ERZ (2000)). Low δ^{34} S values lie within the range considered typical for magmatic values (RYE & OHMOTO, 1974).

The increase of δ^{34} S values with increasing distance from the intrusion characterize the decreasing influence of magmatic sulfur towards the north and an increasing influence of sulfur derived from sedimentary wall rocks. Overall, the δ^{34} S values are independent from the different lithologies of wall rocks, which is attributed to a fluid dominated homogeneous sulfur source, dissolving sulfur out of the magma. The relatively small range in δ^{34} S values within The δ^{18} O values within each deposit and the calculated temperatures are consistent. In contrast, the δ^{18} O values of the several iron ore deposits are different. The δ^{18} O values reveal a dominance of magmatic fluids as described in general by COLE et al. (1983), HAYNES & KESLER (1988), CARTWRIGHT et al. (1997) and BUICK & CARTWRIGHT (2000).

The little difference in isotopic composition of minerals in the ore or skarn bodies, irrespective whether the host rocks are gneiss, limestones or sandstones, and the isotopic trend are attributed to an increasing oxygen isotope exchange with meteoric water at low temperatures towards the north (about 180°C for Rio Albano).

Small variations in the ${}^{18}O/{}^{16}O$ ratios, the lack of crystal-zonation within each deposit (see Chapter 2, 3) as well as the fluid inclusion data (see Chapter 5), argue against variations in temperature and in isotopic composition (ONASCH & VENNEMANN, 1995) and for high fluid:rock ratios without wide rock buffering influence (BOWMAN, 1998).

The multiple regarded two-type distinction of Elbanean deposits (Chapter 2, 3, 4) can be confirmed by isotopic studies: The Ginevro-type has higher Δ^{18} O ratios for the cogenetic mineral pair magnetite-andradite, than all other deposits (hematite-bearing type).

The temperature of ore formation and related wall-rock alteration can be estimated in the range between 600°C (magnetite-andradite) for the Capo Calamita deposit and 180°C (quartz-magnetite) in Rio Albano (Table 5.3, 5.4). The major deposits in the south, Capo Calamita and Ginevro show a pyrometasomatic formation and may indicate the presence of a shallow plutonic body, whereas the deposit of Rio Albano is of hydrothermal genesis, built by temperatures below the critical temperature of water.

The δ^{18} O and the δ^{13} C values of unskarnified marbles and limestone profiles depend on the distance to the skarnified or mineralized contact. The δ^{18} O values of wall rocks are lowest in the ore zone and increase outward, forming a halo several meters in size. The δ^{18} O signature of limestones in several meters distance progressively tends towards unaltered reference samples from the Messinian Rosignano limestones (Table 5.7).

In Elba, the fluid:rock ratios and temperatures were not high enough to allow a significant change in the C isotope composition of the rock. The typical small C isotope halo (VÁZQUEZ et al., 1998) with less than 1 m in diameter, may be related to the chemical composition of the fluid and/or a change in the specification of the C-bearing phases in the fluid with distance from the ore.

In contrast to oxygen, δ^{13} C values of the veins, breccias and interstices are generally different and lower than those of the surrounding wall rock. This difference tends to be larger in greater distance to the ore deposit, suggesting that the fluid flow became more channelized with distance from the ore deposit (VÁZQUEZ et al., 1998). This interpretation is compatible with the suggestion that faults and the major N-S-striking fractures of eastern Elba played an important role in fluid migration and were the focus of fluid flow, as described by DILLES (1982) and SCHULTZ & HAMANN (1985) for the El Mochito mine, Honduras.

Circulating magmatic and meteoric waters contained low initial concentrations of iron (BOWMAN, 1998). This is compatible with the chemical data of the underlying monzonite with low iron content (around 5 wt %). The characteristics of the ore-bearing fluids, which indicate high NaCl content (Chapter 5), imply that the solutions carried large concentrations of iron from the country rocks and that extremely large amounts of water were involved.

As a consequence, physico-chemical variations are responsible for the characteristic Elbanean mineral assemblages of different oxidation stages. Pure temperature effects cannot explain the paragenetic succession and the isotopic data, but a combination of minor varying fluid compositions has been the main trigger.
Chapter 8

Model

On the island of Elba, Italy, the shallow intrusion of a granodiorite pluton into a series of previously regionally metamorphosed gneisses, marbles and marble-bearing schists (Fig. 7.1) produces a contact metamorphic aureole and extensive deposits of Ca-Fe skarns and Fe ores. The Miocene pyrometasomatic to hydrothermal mineralization, associated with skarn formation, precipitated parageneses at temperatures which did not exceed 600°C. As a consequence of the associated increase in rock permeabilities intense metasomatic-hydrothermal activities along the transport channels caused a remobilization of the iron-bearing surrounding rocks and a redeposition in skarns and iron ore deposits (Chapter 4).

Analyses of the observed mineral parageneses show that metasomatism continuously took place under gradually decreasing temperatures, low O_2 fugacity and Fe-saturated, hydrothermal solutions. Fluid inclusion studies prove that the metasomatic fluids were saline brines with dominantly magmatic origin. Oxygen isotope ratios of quartz, magnetite and andradite indicate high fluid:rock ratios. Apparently a saline solution percolated in convection cells preferrably along cracks and fractures in the permeable solid rock system, transporting heat from the plutonic body.

The deposits of Ginevro and Sassi Neri are skarnified and mineralized in an autochthonous position, underlain by the shallow Porto Azzurro pluton. They represent a different type of iron ore deposits comparing to all other: They are free of mushketovite and hematite, show an uncommon skarn association (Chapter 4), less pyrite and no primary carbonate is found (but described from subsurface outcrops). These two deposits are located in the cristalline basement of the Calamita Schists (Complex I), with carbonate-bearing tectonic wedges of Complex II (Chapter 1). Fig. 8.1 and Fig. 8.2 show a simplified model of the autochthonous genesis of Ginevro and Sassi Neri by the Porto Azzurro pluton.

For the second type of iron ore formation, containing Capo Calamita, Terra Nera, Rio Marina and Rio Albano, the data still allow for different genetic schemes, which may be ordered into two alternatives. Both genetic schemes explained below are including pre-Miocene iron enrichment, late Miocene contact metasomatism, Fe-(re)mobilization and ore formation by hydrothermal circulation, based on a fluid-dominated remobilization process of an Fe-rich source rock, depending on the distance to the intrusion.

Two nappes were transported gravitationally while the emplacement and updoming of the Monte Capanne pluton. First the flysch-nappe glided towards the east on the ophiolitic se-

Figure 8.1: Schematic profile of south eastern Elba with the deposits of Ginevro and Sassi Neri with the Porto Azzurro Pluton of quartzmonzonitic composition. The deposits are located in the cristalline basement of the Calamita Schists (Complex I). Scale: Horizontal distance ca. 10 km, vertical distance ca. 1 km.

Figure 8.2: Genetic model for the iron ore formation of Ginevro and Sassi Neri. The late Miocene shallow magmatic-hydrothermal iron remobilization and redeposition preferrably along the east Elbanean N-S-striking fault system is caused by the Porto Azzurro Pluton. The deposits are located in the cristalline basement of the Calamita Schists (Complex I), with carbonate-bearing tectonic wedges of Complex II. Scale: Horizontal distance ca. 5 km, vertical distance ca. 1 km.

Figure 8.3: Geological map of Elba after BARBERI et al. (1967) showing the tectonic complexes, the 6 main iron ore deposits as well as minor skarnified and mineralized localities (black dots), which appear exclusively east of the Monte Capanne pluton. The dashed line outlines the supposed position of the Porto Azzurro pluton (BARBERI et al., 1967; DESCHAMPS et al., 1983b).

quence (Miocene). Later, a second slice, containing parts of the Complexes II, III and minor IV, moved eastwards along the Zuccale Detachment Fault, with a maximal lateral off-set of 5.5 km (Fig. 1.3, NOHLEN (1998)).

The second type ore deposits are situated above the Zuccale Detachment Fault, which is best documented in the Terra Nera deposit and the iron cap of Capo Bianco (a few hundred meters west of Terra Nera), where the cataclasite, the underlying cristalline basement with cut aplitic dikes and the transported ore body are well exposed. Within the Zuccale Detachment Fault only the youngest iron ore generation of syn- to posttectonic specularite occurs, restricting an autochthonous ore formation and determining the end of precipitation.

A first possible setting assumes an ore deposition caused by the Monte Capanne pluton with a subsequent tectonic gravitational transport (from W towards E) by the Zuccale Detachment Fault. In this case the allochthonous deposits of Capo Calamita, Terra Nera, Rio Marina and Rio Albano were mineralized and skarnified at the eastern flank or east of the Monte Capanne pluton.

This genetic model implies iron-bearing sedimentary bedrocks exclusively east of the Monte Capanne pluton, because the thermal aureole shows nowhere else an iron-enriched contact metamorphic overprint (Fig. 8.3) and the granodioritic pluton did not contain enough quantities of iron. Only in the contact zone north-east of the Monte Capanne pluton (locality "Hotel Désirée") occurs minor skarnization, containing wollastonite, vesuvianite, pistacite, diopside and epidote of several millimeters length. Around 1 km south of Procchio an iron cap of several square meters appears in a slice of the Tuscan Unit (Dogger Schists, Complex

III), moved by the first detachment (Fig. 1.3) towards east.

It is to conclude, that iron-bearing sedimentary bedrocks were available exclusively east of the Monte Capanne pluton, resulting in an iron-bearing fluid flow in convection cells east of the Monte Capanne pluton. This corresponds to the locality "Capo Norsi" (Fig. 8.3), where the carbonate-bearing Palombini formation is situated above the Zuccale Detachment Fault. This small fragment of the Ligurian Unit, Complex IV, shows minor contact metamoprhic mineral new growth (wollastonite, epidote, vesuvianite).

These western outcrops (Hotel Désirée, Cap Norsi, Procchio) can be classified as contact metasomatic overprints caused by the Monte Capanne pluton, accompanied by a convective system with overall less iron content in the involved fluid.

For the second genetic model, the mineralization and skarnization of Capo Calamita, Terra Nera, Rio Marina and Rio Albano took place after the gravitational gliding from the Monte Capanne pluton. The iron ore deposits are situated in the Tuscan Units, transported by the Zuccale Detachment Fault up to 5.5 km towards the east, prior to mineralization and skarnization.

The opening of the Tyrrhenian Basin (Upper Miocene) is characterized by a general tendency: The age of intruding magma is getting younger from east to west, showing the oldest pluton emplacement in Corsica (14.3 Ma, BORSI et al. (1967)) and the youngest in the western Tuscan Magmatic Province (4 Ma, SERRI et al. (1991)).

In this model, the transported and warmed nappes (warmed up by the Monte Capanne pluton) were infiltrated by fluid influx from the Porto Azzurro pluton. The remobilization and redeposition of iron from the subsurface did not took place in the present position of the deposits. The fact, that the Zuccale Detachment Fault in Terra Nera is not mineralized apart from specularite reveals a final movement during precipitation of this youngest iron ore generation.

A third possible genesis could be a "mixing type": The main ore forming period occurred east of the Monte Capanne pluton, as described above, followed by gravitational gliding along the Zuccale Detachment Fault. Then a final precipitation of specularite followed in the present tectonic position, founded by the Porto Azzurro pluton. This model is rather unlikely, because the chemical composition of the two plutonic bodies is unequal, but the Elbanean iron ores are almost identical. The absence of iron-bearing host rocks west of the Monte Capanne pluton also argues against this "mixing model". Furthermore, the deposits close to the Porto Azzurro pluton did not show neither hematite nor specularite.

The available data show, that the iron is remobilized from the surrounding sediments, redeposited in six formerly exploitable iron ore deposits. Supposing a Fe-oxide content of 4 % for the Verrucano formation, which is described as a minimal value by DESCHAMPS et al. (1983a) and proved by an exemplarily measurement in this study), the 500 m Verrucano of the Rio Marina Unit (DESCHAMPS et al., 1983a) contains around $100 \cdot 10^6$ tons of iron ore per square kilometer. The output of iron ore in Elba in the main phase from 1820 to 1959 implies ca. $31 \cdot 10^6$ tons of iron ore (MORI, 1961), which equals close to $21.7 \cdot 10^6$ tons of iron (calculated on the basis of hematite). The Veruccano formation (Rio Marina Unit, Complex I and III) with up to 500 meters thickness provides an iron amount three times larger as required to form the Elbanean iron ore deposits.

The δ^{34} S values are typical for a magmatic source and high fluid:rock ratios. The metal content of Elbanean iron ore deposits is primary of sedimentary origin, remobilized from the Verrucano formation and redeposited preferably along main N-S-striking faults, crosscutting eastern Elba. The mineralization and skarnization of Ginevro and Sassi Neri as well as of Capo Calamita, Terra Nera, Rio Marina and Rio Albano took place after the gravitational gliding from the Monte Capanne pluton. The chemical composition of iron oxides and silicates, the high fluid:water ratio, the fluid composition and the isotopic signatures support an one phase formation model for all measured localities and all occurring mineral generations.
